The revetments are likewise proposed by modern engineers to be made vertical, as shown in the profile, fig. 4, experience having proved that perpendicular escarps have some advantages over those to which a slope is given: as on the latter (even on many of Vauban's construction, which have a slope equal only to one-fifth their height) weeds are found to grow, which assist materially in their dilapidation. Many of the escarps above alluded to, in the French fortresses which were built in the reign of Louis XIV., are already, from this cause, falling into ruin: whereas many vertical walls standing near them, and which are of an earlier date, are still in good condition, exhibiting no signs of vegetation on them. It must not from this be concluded that Vauban was unacquainted with the fittest profile for a revetment. In fact, walls whose exterior faces are formed with a small slope, better resist the shock of breaching artillery, than those whose faces are vertical; and it may be added that the construction of the former is more economical than that of the latter, since, with a profile smaller in area, they present an equal resistance to the pressure erected against them by the earth composing the rampart and parapet. It is probable, therefore, that what are called vertical revetments can, with propriety, be only applied at the counterscarps of ditches which are, from their situation, but little exposed to the artillery of the enemy. Revetment walls are now occasionally strengthened by vertical or horizontal counter-arches. The former of these are portions of cylinders standing on their bases and connecting the tails of the counterforts; and their convexities are turned towards the mass of the rampart, that they may be better able to resist its pressure outwards: the latter are disposed in tiers, one above another, and rise from the sides of the counterforts: the arches and counterforts are but slightly connected with the front wall, that when the latter is destroyed by breaching, it may not bring down the others in its fall.

General objections to the Bastion System.

What has been hitherto said of the Systems of different engineers, relates exclusively to those in which the bastion outline has been adopted: but, although that method, with trifling variations, has alone been reduced to practice, it is here proper to notice some objections which have been raised against it. Foremost among the opponents of the Bastion System stands the French General Montalembert. He was, however, not the first: for Werthmuller, A. D. 1685, and after him Landsbergen, Augustus II. Elector of Saxony and King of Poland, Bollersheim, and Herbort, had written upon the superior advantages of a line of rampart which should present a succession of salient and re-entering angles. Into the value of the reasonings which have been offered in favour of such a disposition of the rampart, both on the ground of economy of construction and powers of defence, it is not here our province to enter. But though it may be easily proved that the Bastion System is not without many defects, yet, when the infrequency of opportunities for the erection of entirely new fortresses is considered, it need not excite our wonder, while we avoid to prejudge the question of comparative merit, that the proposed outline has never, in any instance, been practically tried to supersede those methods of fortifying which have so long been in use.

Suggestions of Montalembert for its alteration.

It must, however, be confessed by men of all opinions, that no Author on the Art of Fortification has exhibited greater ingenuity, than did General Montalembert in his numerous and varied combinations of the casemated System of alternate salient and re-entering angles; or in other words, the casemated tenaille System, which he published A. D. 1776. Several enceintes situated within the main ditch; a formidable artillery placed in bomb-proof casemates; and these serving likewise as a cover for the garrison, for stores of every kind, and even for the inhabitants: such is the system which the author proposes to substitute for that of Vauban, the defects of which, he observes, are acknowledged by the best engineers. Vauban clearly showed that his Art of Attack was much superior to his Art of Defence; and he left to posterity the task of remedying the imperfections of the method which he had followed: in attempting which it is evident that two conditions must be adhered to; first, that the new method shall not be more expensive; and secondly, that it shall not require a stronger garrison than the old one. To increase the means of defence under these limitations, is the problem which Montalembert proposes to solve. We shall not undertake to analyze the systems contained in the whole of his eleven quarto volumes, composed, it is said, after he was sixty years of age: but shall confine ourselves to a cursory view of one or two of his principal contrivances, referring the curious reader for the rest to the Work itself.

Fortification.

See fig. 18.

After pointing out the defects of the Bastion System, as executed in most fortresses, Montalembert proposes suppressing the tenaille and curtain, and producing the faces of the bastions inwards to their junction with the flanks of the redoubt in the ravelin, likewise produced inwardly. A hundred toises of rampart would by this means be saved; the flanks would be better covered than they are at present; and their fire would be more certain, because the line of defence would be so much shorter. But if it be desired to preserve the same length of line of defence, by producing the faces outwards an exterior side of three hundred and six toises would be obtained for the side of a heptagon, inscribed in the same circle as a dodecagon whose sides are one hundred and eighty toises long in the Systems of Vauban: whence would result for a defence equal, as he asserts, to the latter in other respects, a saving of one thousand three hundred and thirty-six toises* of rampart in the body of the place. By adding to this the suppression of five ravelins and as many redoubts, there would be economized eighteen thousand nine hundred and twenty cubic toises of masonry. It is true that such a fortress would have but one enceinte like most others in actual existence, which being once perforated would leave the garrison without resource; and for this reason the author proposes, in a second System, said to be *à ailerons*, to form a triple enceinte within the main ditch by producing the curtain to the capitals of the bastions. This enceinte he defends by a casemate placed behind the redoubt of the ravelin; to the faces of which redoubt he adds flanks defending the ditch. The retrenchments of the bastions constitute the second enceinte, which is defended by the wings annexed to the redoubt; and he places a casemated traverse across each face of his ravelin. All the communications between the different works are well covered; and all objection to dead angles is done away with by an appropriate arrangement of casemates. The small space on the rampart of the ravelin, and on that which is substituted for the bastions' faces, will scarcely allow of artillery being placed on

* The toise is equal to 6.3945 English feet.

Fortification.

them by the besieger, with a view of opening the works within: he would besides, in such a situation, be battered in front and in flank within pistol range. Works arranged in this manner, although less expensive and easier to defend properly, are nevertheless greatly exposed to ricochet and shells; and Montalembert, desirous of procuring cover in old existing fortresses from the destructive effects of the latter, proposes making in them the following alterations.

Fig. 19 and 20. He would separate from their rampart the revetment walls of the escarp both of the bastions and ravelins, which may be supposed, as represented in fig. 19, to be those of a front of fortification constructed according to Vauban; and proposes to make the exterior slope of the ramparts of earth. He would lower the escarp walls, (as shown fig. 20,) lengthen the buttresses or counterforts, and make use of them as piers to the vaults which are to cover the batteries; by this he would obtain casemates open in rear and uninconvenienced by smoke. The tenaille is to be suppressed; and the curtain, as well as the retrenchments of the bastions, is likewise to be casemated for both cannon and musketry. A wall of masonry, traverses, and loop-holed guard-rooms, add to the interior defence of the bastions and ravelins. Another species of retrenchment which he proposes, is a casemated tower in the gorge of the bastion, by which the defence may even be continued after the capture of the place. Either one or the other of the above dispositions would, he conceives, oppose almost insurmountable obstacles to the construction of breaching and counter-batteries against them under such a powerful and covered fire of cannon and musketry.

After giving his attention to the means of improving already existing fortresses constructed upon the old plan, Montalembert allows full scope to his genius. He adopts what he calls the TENAILLE SYSTEM; and considering the defence of places to depend upon the greatest number of covered fires that can be opposed to the attack, he places casemates in all the re-entering angles of his

See fig. 21. wet, and also at the angles of his dry ditches. The faces of the tenailles are formed of a double casemated wall, behind which extends an earthen counterguard, whose interior slope falls into a wet ditch. A dry ditch encircles this counterguard and wet ditch, and passes along the foot of the capital rampart, the gorge of which is retrenched by a loop-holed wall, and by a casemated tower with an angular base. A general counterguard, or earthen rampart, surrounds the main ditch; and in its re-entering angles there are casemates, covered by lunettes with casemated flanks placed upon the counterscarp of the outer ditch. The communication from the body of the place to the outworks through the wet ditches is by a cistern-like caponnière, the cover of which serves moreover as a bridge. This double communication may easily be rendered useless to the enemy by cutting away or demolishing a portion of the bridge, and inundating the caponnière by means of sluice-gates at its junction with the place.

The advantages which the Author claims for this system are as follows:

1. The enemy will have to penetrate through four enceintes, of which the three principal ones are within the grand ditch, and under the fire of a numerous artillery unseen, and, consequently, indestructible by the enemy's batteries in the covert-way.

2. The covered fire of artillery which it opposes to the construction of breaching or counter-batteries, is superior to that which the enemy can bring, both in number and in the advantages of cover: so that the execution of those batteries will be a matter of extreme difficulty, if not altogether impossible.

3. Its communications with the outworks are safe; and thus the operations of the troops are greatly facilitated.

4. The tower and loop-holed wall at the gorges of the tenailles, serve as a last retrenchment, when even the enceinte has been carried.

5. The troops and stores are amply and safely covered; and have nothing to apprehend from conflagrations, which too often prove destructive to the defence.

Carnot's System. See fig. 22. The celebrated Carnot was a zealous admirer of Montalembert's talents, and publicly espoused his cause against the enemies of all innovations or improvements in the Art of Fortifying. The construction which he proposes is a System of casemated tenailles covering the body of the place, as in fig. 22. He places at the salient angle of the interior rampart a casemate containing one gun, to batter the saps which may be directed along the capital, and also two pieces of cannon upon each face and flank. The object of these last is to take in reverse any batteries opened against the faces of the collateral salients: two splinter proof batteries accompany the above casemate with the same object. The second enceinte consists of a counterguard merely broad enough for a parapet and banquette, so that the enemy cannot place cannon upon it. Its relief is so regulated that it may cover the casemate at the salient without masking its reverse fires; the covert-way is reduced to the breadth of two banquettes; and a single traverse protects its branches. The ditch of the body of the place is defended by a casemate; the under story of which, A, (see fig. 23,) Fig. 23. receives air by means of a ditch, B: this casemate extends beyond the alignement of the ditch, (see the plan, fig. 22,) in order to see the breach in reverse, and be itself unseen. The upper story alone is continued (on a level with the country) as far as the alignement of the covert-way, in order to defend the ditch of the counterguard: which ditch is terminated by a gradual slope towards the re-entering angle; and here the counterguard is but a mere parapet sufficiently elevated to cover the revetment of the body of the place. An opening is made in this parapet for the egress of sorties, which may also be made through posterns contrived under the shoulders of the counterguards. By this arrangement the besieged have the advantage of being able to make sorties both of infantry and cavalry with great facility, who issue from the ditches by the slope or ramp, which terminates, as already mentioned, at the re-entering angle; and even in the event of a repulse they would derive great protection from the salients. Cavaliers are placed at the gorges of the tenailles, if necessary; and these gorges are closed by defensive barracks and by loop-holed walls, calculated to stand an assault advantageously, or at least to compel the enemy to grant honourable terms of capitulation.

Carnot subsequently recommended a system of works which very nearly resembles that proposed by Cormontaingne. Its principal bastions, whose salient angles are distant from each other four hundred and eighty yards, are, however, detached from the body of the place, and cover a range of casemated batteries at the gorge of each. The bastions are themselves covered by narrow counterguards; and a vast ravelin, having in its interior a lofty redoubt or cavalier, covers the intermediate space. These works are

Fortification.

of earth: but one detached loop-holed wall surrounds the body of the place; and another is placed before the faces and flanks of each detached bastion. This distinguished Mathematician and Engineer here dispenses with the covert-way; and he has made the exterior sides of the ditch to surround the fortress in the form of a glacis, sloping downwards from the level of the natural ground.

The principal means of defence proposed by Carnot consist in a series of engagements with the enemy by powerful sorties; and an abundance of vertical fires, of stones or small balls, made from thirteen-inch mortars placed at the salient angles of the works, and in the casemates in rear of the bastions: by all which the enemy, who is supposed to be collected in great numbers between the third parallel and the place, will be compelled to cover his lodgements with blindages, or roofs made of fascines and earth. A fire of musketry made at an angle of forty-five degrees with the horizon upwards is also recommended for the purpose of annoying the assailants behind their trenches. Among the proposed advantages of this system may be ranked the obstacle which the enemy must experience in passing the loop-holed wall before mentioned, which from its height will be not only difficult to escalade, but more difficult to descend on the interior side; while, being covered by the exterior works, it was supposed to be secure against any attempt of the enemy to breach it. To this may be added, the benefit arising from the countersloping glacis: which is not only convenient from the facility it would afford to the defenders in making sorties; but because it would expose the trenches formed in it by the besiegers to a plunging fire from the ravelin and counterguards. It ought to be observed, however, that the former of these advantages are compensated, by a corresponding facility afforded to the enemy when descending into the ditch to surprise the works; and since the principal ramparts are without revetments of masonry, it is evident that, after the detached wall is breached, which some experiments purposely made at Woolwich have proved possible, the enemy's troops, entering by the breach, may extend themselves along the front of the interior work, and mount in line over its parapet.

PART III.

ON THE MEANS OF INCREASING THE STRENGTH OF FORTRESSES.

CHAPTER I.

Nature of these Means.

Application of expedients for increasing the strength of fortresses.

WHAT has been hitherto said relates only to the construction of different works immediately enveloping the spots fortified; or in other words, to that of the body of the place, with its simple appurtenances of tenailles and ravelins. We shall now show the different expedients by which the strength of this envelope may be increased. But it should first be observed, that many places owe to the nature of their situation such advantages, as it would be difficult to procure by any contrivance of Art. We have a strong exemplification of this in the rock of Gibraltar; and in a part of the country surrounding the fortifications of Luxembourg: at the latter place, a bare rock extending over the accessible ground would, on account of the total impracticability of sapping in such a surface, oblige the besiegers to bring with them from a great distance their means of cover.

Enumeration of artificial means for this purpose.

Art possesses, nevertheless, many resources independent of those derived from Nature, and contributing to the same end. It may augment the duration of the resistance of a fortress by some one or more among the following means:

1st. Interior retrenchments: behind which the garrison, when beaten from the principal works, may renew the defence.

2dly. Counterguards: which must not only be taken, but even destroyed, before the works which they cover can be touched.

3dly. Great exterior works: which, as they cover one or more fronts, force the enemy to a preliminary siege before he can arrive at those points.

4thly. An advanced covert-way: which must be carried before the interior one can be attacked.

5thly. Detached pieces: or works placed so as to command the access to the place, and annoy the enemy with reverse fires.

6thly. Inundations: which drown the enemy's works at the commencement of the siege, and ultimately carry away his fascine passage across the ditch at the moment of his meditated assault.

7thly. Defensive mines, or countermines: which force the enemy to have recourse to the slower and more minute proceedings of subterraneous warfare to make sure his footing upon the surface.

8thly, and lastly. Casemates may likewise be included in this enumeration: notwithstanding the objections which many authors have urged against them.

Of their appropriateness to fortresses of different size.

All these may either be employed separately, or combined in different manners. We may nevertheless observe, that with the exception of inundations and mines, which can be applied to all kinds of places, according as the soil is best adapted to one or to the other, the use of the rest must depend upon the magnitude of the fortress. For instance, interior retrenchments, as they diminish the total space within the works, are but ill suited to small fortresses. Great exterior works, on the contrary, become such places peculiarly, owing to the increased area which they afford for military establishments. The case is far different with counterguards and advanced covert-ways; which, requiring an augmentation of defensive means, without furnishing additional room to contain them, would only tend to multiply the confusion and insufficiency of the interior resources; and such works are therefore only proper for large fortresses. On the other hand, a fortress, which from its size might be accounted of too great an extent, should in preference be reinforced by interior retrenchments.

Fortification.

CHAPTER II.

Interior Retrenchments and Counterguards.

Interior retrenchments.

Interior retrenchments are works either constructed at the same time as the fortress itself, and constituting a part of its system; or else thrown up hastily during the siege to prolong the resistance, by cutting off the part of the rampart breached, and permitting the defence to be commenced anew behind a fresh obstacle. The insufficiency of such works when hastily constructed of loose soil; and the superior advantages which might be expected to result from their being carefully made beforehand, and revetted with masonry both at the escarp and counterscarp; were the reasons which induced Vauban to deviate from his usual mode of construction when ordered to fortify Landau. He accordingly separated the bastions from the enceinte, thereby converting the latter into one great interior retrenchment. Where such means of safe retreat exist, the garrison may with security stand the assault of the body of the place: they are therefore a most essential means of adding to the defence, and by them alone can the besieger be compelled to epaule himself across the ditch, and to make his lodgement upon the summit of the breach; which of all the operations of the siege are the most difficult and dangerous. The case is still worse if the retrenchment be of such solidity as to compel the enemy to use cannon, or the mine, in order to breach it. The difficulty of transporting heavy guns across the ditch and up the breach under the fire of the opposite flank, would naturally induce the besieger to prefer resorting to the latter expedient. But this being of much slower execution, the troops in his works on the crest of the covert-way, or occupied in the passage of the ditch, or in the lodgement on the breach, must all the while be exposed to great loss, under so close a fire of the garrison.

Sometimes composed of a small front of fortification.

These were undoubtedly the considerations which induced Cormontaingne to make in the bastions most exposed to attack, good permanent retrenchments with revetted escarps and counterscarps: and according to the shape of the bastions he regulated that of the retrenchments. When the obtuseness of the bastion left a considerable space between its shoulders, the form which he gave to the retrenchment was that of a small front of fortification: extending between two points taken on the faces at twenty or thirty yards from either shoulder, in order to preserve the whole length of the flanks for the purpose of defending by their fire the ditches and covert-ways of the collateral bastions. A retrenchment of this sort, with a ditch twelve yards wide, and surrounded by a covert-way, having a re-entering place of arms in its centre, would certainly be of great advantage in the defence: particularly if care were taken to give it a command of two or three feet over the faces of the bastions. It would enable the breach in the bastion to be defended with the greatest obstinacy, by the assurance with which it must inspire the troops of a safe retreat, if ultimately overcome. Besides, as the space included by the faces of the bastion diminishes in width the nearer it is to the flanked angle, it follows that, the retrenchment occupying the greatest space, the besieger is always out-flanked and combated by a superior force, during his approaches from the top of the breach towards the counterscarp of the retrenchment: the very reverse of the superiority which the besieger has enjoyed during the whole of the previous operations of the siege. The nature of this retrenchment also entails upon the assailant the necessity of repeating the operations of crowning the covert-way, passing the ditch, and breaching the work, since we have supposed that both escarp and counterscarp are revetted. Such are the difficulties which he must overcome if he should attempt to breach by cannon. If he choose the mine, he may meet with still greater obstructions from the defensive mines which the besieged may have prepared under the point of his bastion. So that, upon the whole, it does not appear that any exterior defence can be preferred to this species of retrenchment, which upon a fair valuation may be considered capable of adding twelve days to the defence; exclusively of the benefit which might accrue from the existence of mines underneath the bastion.

Retrenched cavaliers.

When, by the acuteness of the flanked angle, the interior space did not suffice for constructing the retrenchment in the form of a small front of fortification, with proper dimensions and relief, Cormontaingne gave it the shape of a cavalier. The faces and ditch of the cavalier were defended by *coupures en retirade*, or chequered retrenchments; the foremost of which cut the face of the bastion near the shoulder, and the other was sufficiently thrown back to prevent any part of the cavalier from being dead or deprived of fire. The cavalier had a command of eight feet over the bastion: but the coupures were on a level with the latter. This sort of retrenchment, although much better calculated to second the efforts of the bastion during the early part of the attack, is much less so when it becomes necessary to defend the space between it and the bastion. It therefore merits much consideration as a cavalier, and but little as a retrenchment. As the want of space between the cavalier and the bastion makes it impossible to have a covert-way, the defenders of the breach will not have sufficient room, and their retreat is not made good. The defence will therefore be neither obstinate nor animated. Besides, the narrow space between the counterscarp and the breach may be laid open by the enemy's mines: which will project the rubbish into the ditch of the cavalier, enabling the latter to be breached by the same batteries that breached the bastion, and thereby spare the besieger both trouble and time. It may therefore be repeated that, although this sort of retrenchment has the property of increasing the besieger's loss during the early part of the attack, the first has the more essential one of augmenting the duration of the siege, and making its end more disastrous to the assailant. The cavalier affords, nevertheless, the means of constructing under the mass of its terreplein good bomb-proof establishments; and this may in some cases cause a well-founded preference to be given to it over the other sort of retrenchment, which moreover cannot well be applied to bastions of a small size, owing to the narrow space between the shoulders. Two journals are given by Bousmard of the attack of a cavalier: the first case supposed being that in which there is sufficient space in front of the work for placing breaching batteries; and the second that wherein, from want of room for such batteries, the enemy would be compelled to have recourse to mining, in order to effect a gap for the purpose of breaching through it with the same battery which opened the bastion itself. In the former instance the work is deemed capable of a resistance of only six days, and in the latter of eight: being two days in favour of the smallest space between the cavalier and bastion.

A retrenchment *en tenaille* is made by uniting the

Fortification.

Retrenchments en tenaille.

two shoulders of the bastion,—or rather two points taken on the faces at a few yards from the shoulders,—by two lines forming an obtuse re-entering angle. The ditch of the retrenchment is made ten yards wide, and the escarp and counterscarp, which are of masonry, have a height of eighteen feet. The parapet is on a level with that of the bastion. The communication made in the re-entering part is covered by a traverse, and provided with strong barriers, which is considered a better contrivance than a postern and stairs. But a tambour, or species of redan made with strong beams, may be constructed during the siege, as a tête, or immediate cover to the little bridge of communication. This retrenchment, infinitely more simple and less expensive than those already described, answers the object just as well, for it suffices to arrest the enemy's progress, and induce him to grant a capitulation; at the same time that it affords the besieged more space for an active resistance: that is, by sallying in greater numbers and attacking him in his lodgements, instead of remaining passively behind the parapets.

Rectilinear retrenchments at the gorge.

Another retrenchment still remains to be noticed; and that is the rectilinear retrenchment across the gorge of the bastion. Dufour (a modern author and engineer) thinks highly of it, and appears inclined to give it a decided preference. In the first place, it is economical; and being more distant from the breaches, it defends them better, and is itself less exposed to a sudden attack. Secondly, it leaves the interior of the bastion unincumbered. Thirdly, it may possibly be made to receive a defence from the two collateral bastions; if the besieged take care to demolish a portion of the parapets of the flanks at the moment the assault is to be given. This last advantage will suffice to retard the taking of the place two days: for when the defenders of the breach are compelled to retreat, the enemy's lodgement on its crest will receive a triple battery, two from the collateral flanks and one from the retrenchment itself. This, it is just to suppose, will force him to adopt measures of circumspection of a more than ordinary nature, to avoid being taken in flank when sapping up to the retrenchment. The besieged may therefore securely wait the moment of the enemy's establishing his cannon, to demand a capitulation. An oblique passage may be made at each end, directed upon the angle of the shoulder, thereby avoiding the enfilade from the lodgement on the breach. Each of these passages is covered by a *palanque*, or tambour, to ensure the retreat. The retrenchment at the gorge has the evil of diminishing by one-half the length of the flank: but this is obviated by leaving, entire and full, all that part of the proposed ditch nearest the flank, with the intention, nevertheless, of removing the mass in a moment of need, and of applying it to the formation of those portions of parapet, which, for the above reasons, have also been left incomplete. This will entail but a very trifling increase of labour, as it need only be done in the bastion or bastions attacked; and the trouble will be still less considerable, if the engineer, in constructing the place, has taken care to produce, as far as the flank, the masonry of the escarp and counterscarp of the retrenchment. The only part therefore which will be in permanent existence, is that comprised between the two passages. The two extremities may, until needed, be kept level with the terreplein of the bastion. The defence of a retrenchment thus situated will be more powerful, if the work be constructed in the form of a front of fortification; and, that the flanks of the retrenched bastion may be left entire, it will be only necessary to place the work in rear of the gorge, terminating its two faces in points taken on the curtain at twenty or thirty yards from the angles of the flanks. By this construction also the retrenchment remains unturned, if a breach should be made in the curtain by firing between the tenaille and the flank of the bastion.

Counterguards.

Counterguards are works solely destined to cover others of a more important nature: in such a manner that, without obstructing their fire, they shall preserve them from being breached until the counterguards themselves have fallen. The besieger will likewise be compelled to erect batteries on them, or else partially to destroy them by mines, in order to breach the principal works through the gaps produced from the explosions. The counterguard must, therefore, in the first place, completely cover the principal work, or at least all that part which may be exposed to breaching. It must be lower than the work which it covers, but must, nevertheless, screen its revetment. And, lastly, it must be made sufficiently narrow to prevent the enemy from finding room on it to place his batteries. As for the first condition, that of covering completely the principal works, it must be observed that the counterguards of the bastions, being terminated at the counterscarps of the collateral ravelins, always expose the bastions in rear to be breached through the *trouée* or opening of the ditches of those ravelins: unless, with a view of obviating this evil, counterguards be likewise applied to the ravelins; but then these terminating also at the counterscarps of the counterguards of the bastions, leave an opening through which the ravelins may be breached. It may therefore be considered a radical defect, inherent in such works, that access is always given to the enemy's breaching batteries against one or another of the principal works which they are destined to cover. It is true that the spots where such breaches are practicable, would be but difficultly reached by the enemy, and therefore the evil may perhaps be disregarded: except when it affects the body of the place, in which any kind of breach being productive of serious apprehension, is always dangerous, and seldom fails to serve as a pretence for capitulating. Besides the condition of covering the revetment of the principal works, without nevertheless obstructing their action upon the approaches, the counterguard must have all its interior commanded by the fire of that work. Whence it is evident, that the greater or less degree of command of a work over its counterguard must depend upon the breadth of the ditch which separates them. A work only fourteen yards broad between its escarp and counterscarp will not allow an enemy to construct any battery upon it, if its face be seen from any other which projects beyond it: because he must cut away the parapet of that which he occupies to obtain materials for the epaulement of his battery, and to make room for his guns: and this will evidently expose him to a reverse fire from such collateral work.

CHAPTER III.

Exterior, Advanced, and Detached Works.

Great exterior works.

Great exterior works owe their origin to the desire of occupying some important space in the immediate vicinity of a fortress: as for instance, a neighbouring height; the opposite banks of a river; or, in short, any

Fortification.

portion of ground, the possession of which might procure some advantage, or remedy some defect. Such defences have since been constructed, however, under circumstances which seem to indicate a mistaken notion that, by multiplying the number of works about a place without judgment or discrimination, its strength is proportionally increased. Marolais complained bitterly of the abuse made of these means, and not without reason: since no less than three hornworks were crowded upon one sole front of the small fortress of Juliers, (A. D. 1611,) when the place was threatened with a siege. Besides the immoderate use made of hornworks and crownworks at the period of their invention, the manner of placing them was highly defective. For, their branches being directed upon the body of the place, and their ditches opening into the main ditch, it followed that the enemy, when once established upon the crest of the covert-way of the horn or crown work, could see and breach the wall of the enceinte through the opening of the ditches of the branches. To obviate this defect, Vauban proposed placing them with their branches and ditches directed upon the ravelins, which, however, only palliated the evil by transferring it from the enceinte to the outworks. Great exterior works, nevertheless, were so placed by his directions, for the first time, at Dunkirk, at Fort Nieulai, at Béfort, and at Huningen. The best position that can be given to these works, when their construction cannot be avoided, is beyond the main glacis; having their own glacis blended with the latter, and their gorges well secured against surprise. By this arrangement, the evil of their affording an opening through which any revetment can be breached is avoided; and the enemy will, moreover, after he is in possession of the work, be compelled to repeat the most perilous operation of the attack, that of crowning the covert-way.

Hornworks,

When these works are composed of two half bastions and a curtain, they are called hornworks. When their head, composed of a bastion and two half bastions, forms two fronts of fortification, they receive the name of crownworks. When composed of two bastions and two demi-bastions, the name of double crownworks is given to them: it is evident that the addition of another bastion would produce a triple crownwork. But when these works, instead of being terminated by long branches, are connected with the place by their extreme fronts, which not only defend themselves but are defended by the works of the place, the name of couronnée is given to them. Such are the couronnée of Landau, and that of Yutz at Thionville. The hornwork, if its ditches open into the main ditch, and its branches rest upon the body of the place, unless there be some circumstances of peculiar advantage in its situation, would rather weaken than add to the defence. If its ditches open upon those of the ravelin or other outworks, it may add six or seven days to the siege. It will add twice as many if the work be placed beyond the glacis, as above mentioned. The crownwork, although it has two fronts, adds nothing to the resistance of the part which it covers, if its ditches expose the walls of the latter. If placed upon outworks it may prolong the defence about eight days; and twice as long, if placed beyond the glacis. The double crownwork, as it consists of three fronts upon a straight line, or on a line nearly straight, is capable of a much better defence, and will even add to the resistance of the place, although its ditches should open into that of the latter. This increased resistance may be fairly estimated at eight days, when the ditches open into those of the outworks; and at twice as many when they only open upon the glacis. The couronnée, indeed, as it may be considered in the light of a portion or segment of a fortress, may possibly be stronger than the place itself: this, however, will depend upon the manner in which it is applied. If its ditch is made to open into the main ditch, it will be defective: but this junction is generally so contrived that the trouées or gaps may not enable the enemy to breach through them. In the former case, the only delay will be that required for erecting breaching batteries in spots where they may act through those gaps, and this will but amount to five or six days, which will be doubled if the couronnée rests or is directed upon outworks. In short, the full influence of the couronnée, in adding to the resistance of the works which it covers, will only be felt when it is placed beyond the glacis. The above estimate of the value of the different great exterior works, is that given by Bousmard, in his *Essai Général de Fortification.*

Crownworks,

and Couronnées.

Advanced covert-ways.

If, in consequence of a rivulet passing along the foot of the glacis, the making of sorties from those fronts should become a difficult operation, it is usual to construct, on the other side of the stream, another covert-way performing the same office as the original one. In it are placed the advanced posts to watch the enemy's movements; troops destined to act upon the offensive are assembled there to make their preparations for the attack; and they retreat into this advanced covert-way as into a place of refuge in the event of discomfiture. If the advanced covert-way is situated before a portion of the enceinte, the fronts of which are nearly on a straight line, and if its salients are supported by advanced lunettes, it will give the enemy as much trouble to take it as the original covert-way itself. The place will therefore experience by this addition to its works a sensible advantage: since the besieger, after capturing the advanced covert-way and lunettes, must renew operations upon the inner glacis against the ravelins and their covert-ways. The advanced covert-way, besides affording the lunettes security against a surprise and their salients an immediate defence, renders them more efficient works, and capable of a more protracted resistance than if not so enveloped; and these properties in the advanced covert-way have caused it to be employed as a means of increasing the strength of a place, even in cases where no such necessity existed for occupying ground beyond a rivulet. But these advantages only exist under the particular circumstance of the fronts being developed upon a straight or nearly straight line, with their extremities resting upon natural obstacles. For without these conditions, the advanced covert-way which might surround a fortress altogether, as it would have a developement much greater than the ordinary covert-way, would likewise have branches longer and more liable to the ricochet. To this disadvantage may be joined that of being only defended by the lunettes; as the fire of the place must cease as long as the advanced covert-way is occupied. The great distance between the salients, which should afford each other a reciprocal defence, may also be mentioned as a serious defect. A work of this kind may, therefore, without much difficulty, be carried by storm, and would require the besieger to make but two parallels, and to break ground at a small distance from the salients. From which it appears that the construction of a general advanced covert-way round

Fortification.

a place, at least when fortified on an inferior polygon, would be productive of no real benefit to the besieged; and the expense would nevertheless be greatly increased. We may therefore (says Dufour) establish as a principle, that an advanced covert-way can only be made before a portion of the enceinte not likely to give it an excess of developement, and that even then care must be taken when constructing it: 1st, That the narrowest space enclosed between the two covert-ways shall not be less than sixty yards wide. 2dly, That every part of its counterscarp shall be revetted; and that this revetment shall be of a nature to force the enemy to make a descent into the ditch, and shall put it out of his power to surprise and storm the lunettes at their gorges. 3dly, That the places of arms be provided with small redoubts in which the defenders of the salients may find a safe retreat. 4thly, That the advanced covert-way be not as high as that which it surrounds, in order that the enemy, when he has reached the crest of the former, may be unable to see into the latter. 5thly, That the faces of the lunettes be always flanked by the salient parts of the ravelins or bastions. It is no easy matter to adhere to all these conditions on a level country; and it can only be done by giving to the covert-way of the place a more than ordinary degree of relief, and by producing its glacis beneath the natural level of the soil, as far as the counterscarp of the advanced covert-way, thereby enabling the latter to have a greater height. The glacis of the advanced covert-way may in a great measure be formed of the earth so excavated. Recourse may be had to this method of lowering the ground by producing the glacis, for the purpose of establishing lunettes of which the gorges shall have sufficient height to prevent escalade, without elevating their crests too much above the level of the country.

Lunettes.

The lunettes above alluded to are a species of ravelin usually placed upon the salients of the covert-way to flank the approaches. Where there is an advanced ditch, the lunettes are placed upon its borders, but where no such ditch exists, they are situated at the foot of the glacis. The lunettes themselves have a ditch twelve or fifteen yards wide, surrounded with a covert-way, to screen their revetment from the enemy's distant batteries and prevent them from being stormed at the gorge. A series of good lunettes judiciously disposed, should afford an excellent defence. It is calculated that such works, on polygons of ordinary size, may add ten or twelve days to the defence, and considerably more when the angle of the polygon is very obtuse. Their advantages are chiefly these: they compel the enemy to break ground at a much greater distance from the place; and as a preliminary siege must be gone through to take them, ere that of the place itself can be said to have commenced, the defence is prolonged by all the time consumed in their attack. These works are, nevertheless only adapted to large fortresses; as they need an employment of troops and artillery beyond the limits of the enceinte, which a numerous garrison alone could afford. If the lunettes are surrounded with a dry ditch, it is absolutely necessary to revet them with masonry: otherwise a few rounds of the enemy's cannon would soon lay waste the fraises or inclined palisades, and they might be assaulted without further trouble. But, where a wet ditch surrounds them, the expense may be spared, as no such danger need be apprehended.

Flèches.

A smaller and much less important work than the lunette is often placed at the foot of the glacis. It is made in form of a redan,* and the name of *flèche* is given to it. The faces of the flèche are usually made twenty-four or twenty-five yards long. Its object is to support and flank an advanced ditch, or advanced covert-way. When the glacis of a place is very steep, and the covert-way of more than ordinary relief, the flèche is of great use, because its fire acts upon spots unseen from the covert-way; but when the latter has but a small relief, the flèche may be omitted, as its relief may obstruct the fire of the covert-way, and enable that of the enemy to plunge into the latter work when he is in possession of the flèche.

Advanced ditches.

When the site of a fortification is low and marshy, and it becomes impossible to give the ditches the necessary depth for furnishing sufficient earth wherewith to construct the covering masses, a second or advanced ditch is excavated at the foot of the glacis, which will make up the deficiency and obviate the necessity of going to a distance to obtain it. Although the advanced ditch serves as an obstacle and prevents the enemy from arriving at the covert-way, it is, nevertheless, far from being a good work when isolated as is the case in many fortresses. For if, on one hand, the enemy experiences a difficulty in getting across it, the besieged, on the other, feels great inconvenience when making sorties, as he must pass over bridges, troublesome to construct and easily demolished by the enemy's distant batteries during the first days of the siege. There are, nevertheless, some advanced ditches possessing great advantages: we allude to such as may be kept dry, and suddenly flooded at the will and pleasure of the besieged. The latter would thereby derive all the benefit resulting from an uninterrupted communication during the early part of the siege; and when the ditch falls into the enemy's hands he may suddenly let the water into it. These cases, however, are rarely met with. If the nature of the localities be such that it is out of the enemy's power to drain the wet advanced ditch by cutting a canal and turning the water into it, the bed of the ditch may be made in any manner whatever. But where the possibility of such a thing is at all a matter of doubt,—and it is impossible to ascertain the fact otherwise than by the nicest levellings,—the slope of the glacis must be produced to form the ditch: in order that the enemy may not find any cover there when he has drained and occupied it. It is impossible to fix the breadth to be given to advanced ditches: it must depend upon their form; the nature of the ground; and the quantity of earth necessary for the construction of the works. But the wider they are the better.

Detached works.

The name of detached works is given to such as are unconnected with the fortifications of the place, either by an advanced covert-way, or in any other manner. The chief object of these works is, to obtain reverse fires upon the enemy's approaches at the time of his attack upon any of the neighbouring fronts: so that he may be under the necessity of reducing the advanced or detached work, ere he can undertake the siege of the place itself. Now the taking of a detached work is any thing but an easy operation, if from the nature of the situation it can in a manner be rendered inaccessible; and this will be the case if it is situated in the midst of

* See *infra*, Field Fortification.

an inundation. Supposing it to be so placed, it will still be well, in order to secure it from surprise by boats or rafts, to surround it with a covert-way or dike, separated from the work itself by a wide and deep ditch. Those parts of the work which are to afford the reverse fires above alluded to, should be so constructed as to be screened from the ricochet fire of the enemy's batteries; and the detached work should be placed at a distance of one hundred and fifty, or one hundred and sixty yards, from the edge of the inundation, to be beyond the range of the mortars used for throwing stones or small balls. Its parapet should, moreover, be twenty-four feet thick, to render its demolition a matter of greater difficulty to the besiegers.

Besides ground of such a nature as will admit of being inundated, there are many other situations in which a detached work may be rendered inaccessible to the enemy; or at least, in which he shall be compelled to the developement of extraordinary means ere he can hope to reduce it. When placed upon a steep rock, too hard to be either breached or mined and too elevated for the escalade, it may be considered inaccessible; and it would, moreover, have the advantage of commanding reverse and plunging fires, from which nothing within a considerable distance could escape. A detached work may likewise be deemed inaccessible when built upon an extent of flat bare rock, on which the enemy could neither dig trenches nor sink shafts of mines; and the difficulty of reducing it will be greater, if care has been taken during the leisure of peace to establish underneath its glacis, by dint of labour and blasting, a good system of defensive mines. The bastion fort of La Lippe, at Elvas, in Portugal, is of this nature; as are likewise the detached works at Luxembourg: both of which are worthy of being studied by professional men.

It is not, however, always possible to find situations which almost of themselves shall render a detached work inaccessible: it will therefore be necessary to compensate for any local disadvantage by creating all the artificial obstacles that can be raised. In the first place, the work should be revetted with masonry both at the escarp and counterscarp. The former should be at least fifteen feet high, and crowned at top with a row of inclined palisades as a security against escalade. Behind the revetment of the gorge (if the work be in the form of a lunette) a loop-holed gallery should be made, having the crown of its vault on a level with the natural ground: in order that it may be secured from destruction by shells. The loop-holes should be as low as possible, that the fire from thence may be more effective, and that the enemy may be less able to fire through them into the gallery. But the most powerful way of adding to the strength of such works is unquestionably that of subterraneous fortification.

In almost every case the position of a detached piece is determined by the localities of the ground, by the nature of the defences of the place, and by the particular object of the work itself. If the latter be intended to have a reverse fire upon the neighbouring fronts, it may require to be placed on such elevated spots as command a view of the acclivities leading to those fronts. If, on the other hand, the object be to see into the bottom of a valley, a site must be chosen for the work at the beginning of that valley. When, in order to fulfil any of these conditions, the work is necessarily placed too far from those of the fortress to derive from the latter a musketry defence, another or intermediate work must be thrown up halfway between them to render it that service. And as this intermediate work is defended by a close fire from the place, and protected against the first fury of the enemy's attacks by the work in advance, under the fire of which he must pass to arrive at it, it need be but a simple flêche, or at most a small lunette. To prevent, however, its falling by the same attack which might be directed upon the gorge of the detached work, it is necessary to palisade its escarp and counterscarp, and to close the gorge with a strong loop-holed palanque.

There may be cases in which, from the nature of the ground, the detached work will not suffice to fulfil the object in view. For instance, when the elevated ground on which it is to stand, is too broad to enable both its sides to be sufficiently discovered by the work. It then becomes necessary to construct two or more works of the kind; or as many, in fact, as shall completely occupy the whole plateau, and have a good reverse view of the ground by which the enemy must approach to the neighbouring fronts of the place. It, in short, is preferable to occupy the plateau by a series of detached works, rather than to enclose it with one great exterior work. For these isolated works, having in rear of their gorges an open space where bodies of troops may conveniently assemble for sorties, and from whence they may proceed without the embarrassment and delay of filing through the barriers of a covert-way, offer greater advantages for those important enterprises than can a continuous exterior work. The retreat into the latter, when the sortie has effected or lost its purpose, is also slow and troublesome: whereas the intervals between detached works are so many broad and safe passages, through which the troops may speedily retire under the protection of the fire of those works.

CHAPTER IV.

Inundations.

Inundations.

One powerful means of adding to the value of fortresses consists in the employment of water in inundating the adjacent country to a vast extent, and in producing in the ditches of the place such sudden and violent torrents that the enemy's works shall with great difficulty be able to resist their impetuosity. The first effect of a bank thrown across a river, is to produce on the flood side an inundation which will be more extensive in proportion as the dike or dam is high, and the slope of the surrounding ground gentle. By this means the fronts of fortification on the flood side will be in a great measure covered and rendered inaccessible; thereby leaving to the enemy the only remaining alternative of attacking either the fronts on the ebb side, or those lying intermediately. But if, by a sudden removal of the dike, all the water is allowed to rush at once to the ebb side, the river's natural bed being insufficient to contain it, the country must of course be inundated: so that, if the enemy has chosen to attack on that side, his trenches will be swamped and his ammunition destroyed. Hence, when the waters of a river are judiciously managed, the enemy will be forced to avoid its banks both on the upper and lower sides, and to attack the intermediate fronts: upon which a greater expense

in defensive dispositions may be better afforded. Again, it sometimes happens that the waters of an inundation, by rising to a certain height, run off the sides and spread themselves in the country, gradually making the circuit of the town, (either on one or on both sides,) and find their way ultimately into the natural bed of the river. Should the temporary river thus formed be of a good breadth, all the works which it encloses will be protected from the enemy's attacks: but this seldom is the case, as the banks of rivers are usually higher than the dike; and the waters therefore flow over the latter, and continue their course as usual.

The bridge over a river, for communicating from one to another part of the town, is usually converted into a dike by stopping up the arches with sluice-gates: precautions must in this case be taken to prevent the undermining which the fall of the water might produce on the ebb side; and the piers of the bridge ought to be of sufficient strength to be able to resist the pressure of the water. The closing of the arches is, as above mentioned, effected by two sluice-gates, which fall into grooves made in the piers, and are worked by levers or screws in such a manner that they can be quickly and simultaneously uplifted, when it is required, to let loose the torrent upon the enemy's attacks. The besieger, who is usually acquainted with the spot where this contrivance exists, will of course direct against it a great profusion of shells; and it is therefore advisable to have double flood-gates under each arch: so that, if one gets damaged, the remaining one may perform its office. An inundation would also be useless if it were at all in the enemy's power to drain it: that is, to dig a canal into which its waters might be turned. This, however, may sometimes be prevented, by constructing a work near the spot where it is most likely to be done. Such a precaution is more particularly necessary when the drain, in emptying the inundation, might at the same time deprive the place of the water indispensable for the subsistence of the garrison and inhabitants: there being instances of a place surrendering through thirst, which by the nature of its works, and strength of its garrison, might have been expected to stand a long siege.

The advantages resulting from the employment of water as a means of defence do not consist solely in inundating the country about the place. It is likewise in some cases possible to introduce water suddenly into ditches habitually kept dry: whereby all the works, which the besieger may have executed for the purpose of reaching the foot of the breach and facilitating the assault, may be entirely destroyed. When this torrent has subsided, and the smaller rubbish of the breach has been removed by it, leaving only the larger fragments, the breach may be no longer practicable; and the besieger, to render it so, must recommence battering and forming his passage: which—as he will have just reason to apprehend a fresh disaster of the same nature—he must make with the solidity of a real dike capable of resisting the weight of the torrent, and of sufficient height to cause a reflux of the waters. But as all this will require much time and labour, the besieged may leisurely take measures for defending the breach with the utmost obstinacy. The manner, in which these artificial torrents are produced, is as follows. A dike with gates stretches across the river at its entrance into the town, which is generally between two bastions constructed on the opposite sides of the river; and the dike is made high enough to allow the inundation to be six feet above the bottom of the ditch. Then, at or near the place, where the main ditch of the fortress branches out from the river, on the ascending side, gates are formed across the ditch to admit or exclude the water of the inundation; and these, which must be made higher than the dike across the river, to prevent the water from flowing over them, are provided with a bomb-proof cover to secure them from the effect of the enemy's shells. Other gates are formed in like manner at the communication of the ditch of the fortress with the river, on the descending side, and serve to retain the waters in the ditch, or to let them escape, as may be required. The former, for distinction's sake, may be called flood-gates, and the latter ebb-gates.

When the enemy has effected his descent and irruption into the ditch, and has commenced his passage across it, the defenders cease to dispute the passage, and open the flood-gates, leaving the ebb ones closed. The ditch will then fill with water, which, washing down the enemy's epaulement, may compel him to raise his gallery of descent, and commence, in all probability, a fascine bridge, to avoid a repetition of the torrent. This bridge (which is of the lightest kind and moored with small anchors) may have nearly reached the rubbish of the breach, and every preparation may have been taken for the assault; when the besieged, by suddenly opening the lower sluices or ebb-gates, produces a torrent through the ditches which will remove a good portion of the rubbish, and loosen and damage the bridge of fascines. But a still more violent shock is at hand: the upper sluices are thrown open, and the waters rush in with an irresistible impetuosity; carrying away the bridge, and probably discouraging the enemy from any further attempt to overcome so powerful a means of resistance.

A pair of additional sluice-gates may be made somewhere between the two former, to obviate the inconvenience which might result from an accident happening to one of those, and also to augment the force of the current in the ditches on the descending side. The gates are generally placed across the ditch in the direction of the capitals of the bastions, where they are less exposed to the view of the enemy when he has crowned the glacis; and ebb-gates should be made wider than the others: in order that the water may be less retarded in its escape, and any diminution in the force of the current avoided. In order to secure the advantage of using the ditches as dry ones during the first days of the siege; and particularly to afford the means of communicating freely with the exterior works, and of making repeated and vigorous sorties; it is necessary that the bottom of such ditches be about one foot above the ordinary high-water mark in the river. A cunette, or small drain, is dug along the ditches of the place in order to carry off the water, which (even when the gates being closed the great mass of it is excluded) will inevitably filter through the masonry of the dikes. To procure to the currents in the ditches all their desired effect, it is necessary that the sluice-gates be made to open promptly and give a wide entrance to the water. Of all the means as yet proposed, to arrive at this desideratum, the most simple is that contrived by M. de Bousmard, which, although it has never perhaps been tried, is very ingenious, and deserves to be here described. He proposes two piers, with a door between them turning upon a vertical pivot or axis, which is placed so as to divide the door into two unequal parts. The pivot is firmly secured at top by a cross beam or otherwise, and at bottom by a flat stone into which it is

Fortification.

let. The door being unequally divided, it follows that the stream presses more strongly (the volume of water being greater) on the largest of the wings; and this, as it rests against a groove in the quay or pier, naturally keeps the gate closed, and excludes the water. But on the above-mentioned largest wing there is a small door which can be opened by such machinery as is used in the apparatus of canal locks. The opening of this small door reduces the surface of resistance to less than that presented by the smallest of the wings. The consequence is that the greater pressure being thrown upon the latter wing, the gate turns upon its axis or pivot and gives free ingress to the torrent of water.

CHAPTER V.

Defensive Mines.

Mines.

The Art of mining, as practised in the Ages of Classical Antiquity, appears to have undergone no change for nearly two Centuries after the invention of gunpowder. A Genoese engineer, at the siege of Serezanella, A. D. 1487, was the first who tried to substitute the use of this destructive ingredient for the old method, but did not succeed. The celebrated Pedro Navarra, then a private soldier, who was present at this siege, on being afterwards received into the Spanish service and raised from the ranks, repeated the experiment with as little success at the siege of Cephalonia. Not discouraged by these failures, he tried it again at the attack upon the Castel del Ovo at Naples, A. D. 1501, and acquired, if not the credit of being the inventor, at least that of being the first who had applied this new means with success. Before Bologna, (A. D. 1511,) Navarra again tried his mines, but a singular accident is said to have rendered them abortive: the mines were sprung and the wall was uplifted; but, if the tale may be credited, the whole mass fell again upon its base, offering to the astonished beholders no other proofs of its having quitted its foundation, than the crevices where the separation had been effected! The besieged proclaimed a miracle: but Navarra explained the apparent prodigy, by showing that the charges had been placed with too great precision under the centre of gravity of the masonry.

In order that the reader may the more easily understand the phrases which we shall have occasion to use in the following pages on modern mining, we shall begin by a few definitions. Any subterraneous excavation, made with a view of containing gunpowder for the removal by explosion of the objects on the surface, is called a mine. The place where the powder is deposited is styled the chamber. This chamber is of a cubical form, and of a size proportioned to the magnitude of the intended charge. The excavation produced by the explosion is termed the crater. The line drawn from the centre of the charge to the nearest point upon the surface, whether the latter be upon an horizontal or inclined plane, is technically distinguished as the line of least resistance. The subterraneous roads conducting to the chambers of mines are denominated galleries. These are divided into grand galleries, demi-galleries, and branches. Great galleries are six feet high and three wide in the clear; demi-galleries four feet by three; and the branches three by two and a half. The largest of these galleries may vary in their dimensions according to circumstances: but for reasons which will be explained, it would be improper to alter the dimensions of the branches. The great galleries are the miner's principal roads; and every thing is conveyed through them: the demi-galleries are the communications from one to the other of these roads; and the branches are the small paths which lead from the galleries of communication to the chambers of the mines.

System of permanent defensive mines.

The galleries which usually constitute a simple system of defensive mines are situated as follows. The gallery of the escarp is so called from being situated at the back of the wall which supports the rampart. The object of this gallery is to enable the breach to be more obstinately defended by the explosion of small mines placed under the rubbish at the moment of assault; thereby destroying the assailants, and restoring to the breach its original steepness. It is hardly necessary to say that when this is done, the enemy is compelled to batter the rampart anew. This gallery, moreover, serves to defeat the enemy's attempts to breach by mine, in the event of his preferring that means to battering with cannon, or if he should be disposed to employ both. With respect to dimensions, this gallery of the escarp is of the largest above mentioned; and its situation is shown both in the plan and profile. See pl. iv. fig. 2 and 3.

Another gallery extending along and underneath the covert-way is called the counterscarp gallery. Its situation has been considerably varied according to the opinions of the different contrivers of Systems. Some have placed it underneath the banquette of the covert-way; some under the middle of the terreplein; and others again close behind the counterscarp wall. The latter disposition seems to be more generally preferred, as most economical, most easily lighted and aired, and furthest removed from the influence of the enemy's explosions. The lighting and airing here meant are obtained by loopholes cut in the revetment of the counterscarp which, besides, enable a reverse fire to be had upon the enemy when he may have penetrated into the ditch: the entrances into this gallery are provided with stout oaken doors with bolts on the inside. Many authors, however, object to this situation for the counterscarp gallery: alleging that, when the enemy has possessed himself of it, the very contrivance for affording a reverse fire along the ditch, will serve him to keep in check any sorties which the defenders may make to dispute his sap or passage across the latter. The entrances into this gallery are most frequently made in the counterscarp wall near the re-entering angles of the latter; and, in that case, a tambour is made upon the terreplein of the covert-way enclosing the stairs at the re-entering angle. This measure of security is, however, unnecessary when the re-entering places of arms are (as in the modern and Cormontaingne's Systems) provided with a redoubt. Besides this precaution, it is well to have a caponnière on each side of the entrances, to flank the accesses to them along the main ditch and that of the ravelin. When the soil is dry enough to admit of it, the safest way of communicating into the counterscarp gallery is by a gallery of communication passing from that of the escarp underneath the ditch. This procures, moreover, the advantage of enabling a branch to be driven from it under any spot where the enemy may be making his passage across the ditch: besides affording security against any attempt to seize upon the galleries by a sudden attack.

A gallery running parallel to that of the counterscarp at a distance of about forty or sixty yards from it—that is, about the distance of the foot of the glacis—is called the envelope. It communicates with the former by others, situated under the ridges and furrows of the glacis, and which are denominated galleries of communication. The gallery of envelope is omitted in most Systems, because, presenting an extensive front to the enemy, it is speedily destroyed by his first explosions; and it is urged that mere passages terminating in a point, or by a portion of envelope, so as to resemble the letter T, are more advantageous: as they not only answer the same purpose of enabling the defender to commence early his dispositions for intimidating the enemy; but the destruction of one portion would not entail that of the neighbouring one, or facilitate the enemy's attempts to introduce himself into the galleries after an explosion. But, in any case, from the envelope there are other galleries extending into the country to a distance of about thirty yards; placed at intervals of fifty yards; and called listening galleries, or listeners, from their object, which is to enable the besieged to anticipate his enemy by watching his approach under ground. The distance to which it is possible to distinguish sounds, must of course depend very much upon the more or less compact nature of the soil: but, in ordinary cases, the blows of the excavating tools may be heard at a distance of thirty yards; and those of the hammer in fixing the framework at forty or fifty. The reason, therefore, for placing the listeners fifty yards asunder, is obviously to render it impossible for the enemy to penetrate between them unheard, either from one side or the other. The means resorted to by the miner of the besieged to assist him in listening, are various. He may lay a plate of sheet iron flat against the side of his gallery, and apply the ear to it. He may drive a trepan hole in the most likely direction, and listen through it; and if he has any reason to apprehend that the enemy will attempt to pass under him, a pea, or any round body, placed upon a drum head, will vibrate at the blows of the pick and betray the design. At certain distances along the whole of these galleries there are ready-made doorways, merely filled up with loose bricks. These are also called listeners, as they serve for that purpose, and enable the defenders to drive branches, without loss of time, in any particular direction. To prevent the enemy from obtaining possession of the whole of the galleries in the event of his succeeding in getting into a portion of one, care is taken to partition them off with strong oaken doors, having loopholes with shutters in them, through which a fire may be directed against the besieger, or stink balls thrown to smother him. The galleries of communication are likewise separated from the principal galleries by doors of the same material; but these slide back into a groove in the wall, instead of turning on a hinge, which from the nature of their situation would be inconvenient.

Listening galleries.

It often happens that no system of defensive mines has beforehand been made underneath certain fronts of a fortress, which nevertheless may require such an expedient: in order to establish an equilibrium of strength between them and the remaining fronts. The manner in which the establishment of such mines is effected at a moment when a siege is anticipated, remains to be described before any thing is said respecting the charges of mines. The first thing done is to determine, upon the plan of the works, the situations which it may be most expedient to allot to the several galleries. It is unnecessary to observe that, here care must be taken not to run into useless expense and loss of time, for the mere sake of symmetry. The galleries must be made underneath those spots upon which the enemy is obliged to conduct his saps; and it would be needless to drive them in places where, being seen in reverse by some projecting outwork, he would never attempt to approach. When these points are settled, the plan thus devised upon paper is marked out upon the surface of the ground, and at all the intersections of the lines denoting the situations of the intended galleries, shafts are sunk. The reason for sinking shafts at the intersections is, that any inaccuracy of direction in the driving of the galleries may thus be the more easily corrected: as, when the shafts have arrived at the required depth, the galleries are driven from thence to meet one another between every two shafts.

The materials used for sinking the shafts are square or oblong frames, with a sheeting of planks to prevent the earth from falling in. The operation is commenced by placing one of the above frames (with projecting ends of a foot or fifteen inches length) flat upon the ground, with two of its sides at right angles with the line denoting the direction of the intended gallery. The frame is fixed so as to be immovable; with pickets or stakes driven in on each side of the projecting ends. The miners now commence digging; and the depth of the excavation must depend upon the greater or less tenacity of the soil. In ordinary soil, the second shaft frame may be placed at a depth of four feet. When, therefore, the miner has dug to this depth, he makes the bottom of the shaft perfectly even and level, and then places the second frame (of course without projecting ends) vertically under the first, and ascertains its position with a plumb line. This done, he connects the first frame with the second by means of wooden ties of equal length, nailed to the centres of the sides of the frames. The sheeting is then introduced between the frames and the earth; and wedges are placed between the sheeting and the second frame to preserve room for slipping in the planks from the second to the third. Any cavities between the earth and planking are filled up with sods or sand-bags: in order that the sheeting may press firmly against the frames. The digging is now recommenced and continued to the same depth: when the framing, sheeting, and adjusting are repeated. As long as the excavation is sufficiently near the surface, the loosened earth is easily thrown up by manual force; but in proportion as the shaft becomes deeper, other means are resorted to for its removal. A cylinder, turned by a winch, like the machine used for drawing water out of a well, answers the purpose sufficiently, by passing several times round the cylinder a rope having a basket or bucket fastened to each of its ends: by which means one ascends loaded whilst the other descends to be filled. When the shaft is sunk to its required depth, the sides of the two last shaft frames, situated in the direction of the intended gallery, are removed; and the excavation of the latter is commenced, either horizontally, or with the inclination suited to the object in view.

Pl. iv. fig. 4.

In the driving of galleries, the means of keeping up the earth are much the same as those employed in sinking shafts; frames and sheeting being employed for the purpose. The former of these are composed of two stanchions, a capsill, and a groundsill; the latter is sometimes omitted, but such a practice is not to be recom-

Fortification.

mended. There are, however, many cases where sheeting is not altogether indispensable; as when the soil is sufficiently stiff to support itself without such assistance. The frames by themselves are then used; and even these are often dispensed with, in strong soils, and where the mines are intended for immediate use; it is nevertheless scarcely justifiable to put men's lives into jeopardy, merely to economize a few pieces of timber, or the few additional moments which the fixing of the latter might require. When these galleries are made, as here supposed, at a moment of need, it will suffice, in order to save trouble, to give them four feet and a half of height, by three, or two feet and a half, of width. When a branch only is driven from one of the above galleries to the place where the powder is to be deposited, it may be made three feet high, by two and a half broad: there is nothing gained, with respect to time, by making it smaller; for if, on one hand, there is less to excavate, on the other, the inconvenient posture of the miner, who even in a gallery of the above dimensions is obliged to work sitting, will render the progress of the work nearly the same. But there is an important reason for not increasing the dimensions of the branches:—that the smaller they are made, the more readily and solidly may the mine be tamped, and the less likely will it be, that any part of the charge should find vent along the branch. The earth is removed from these branches by means of a small four-trucked cart, having a cord at each end. In proportion as the first miner excavates, a second draws the earth towards him with a hoe, and fills the little cart; which is then drawn by a third to the entrance of the branch; where the earth is received and transported to a greater distance, or to the foot of the shaft, by a fourth. Four miners thus employed constitute a brigade. When it is necessary to fix the framework, the whole four assemble for the purpose. It has been found, by repeated experiments and by actual service, that brigades of miners, relieving one another at proper periods, can execute on an average eighteen feet length of gallery in twenty-four hours: this supposes, however, that nothing occurs in the way of obstruction from the enemy to cause any delays.

See fig. 5. plate IV.

The distance, at which the frames are placed in the driving of galleries, is determined by the same reasons which regulate the intervals of the shaft-frames. Some soils, as we have already said, are stiff enough not to require these supports: but, again, there are others which are so loose as to oppose almost insurmountable difficulties to the progress of the miner; and there are indeed cases where, the soil being sand or gravel of the loosest kind, no other alternative remains but to cut out the gallery like a ditch, open at top, case up the gallery carefully with sheeting, and then fill in the soil over the top. It must, however, be observed, that a gallery having but one issue cannot properly be driven beyond a certain limit, without inconvenience or danger to the miner; the air, from want of ventilation, not being proper to support life. When, therefore, it is necessary to go beyond that limit, some means must be employed to produce an artificial current of air. The most common expedient is that of a forge bellows placed at the top of the shaft, and having canvass or leathern pipes extending into the gallery or branch.* A trepan hole may likewise be driven, from the ceiling of the gallery up to the surface of the ground, for the same purpose. When a branch has been driven to the required length, a return is made at the end either to the right or left, and the chamber is excavated. The reason for making the chamber in a return is that the mine may be more solidly tamped; and this is done in a manner to be presently described.

The quantity of powder with which the mine is to be charged must of course depend upon the effects required to be produced, and upon the nature and tenacity of the soil in which it is to act. The immense number of experiments made by De Valière enabled him to arrive with great accuracy at the conclusion, that a cubic fathom of soil of ordinary tenacity required ten pounds, ten ounces, six grains of powder to uplift it. Then, on the supposition that the crater of a mine is a paraboloid, having the diameter of its base equal to twice the line of least resistance, and the focus of its generating parabola at the centre of the charge, he calculated the cubical capacity of the excavation in fathoms; and, consequently, multiplying ten pounds, ten ounces, six grains, by that number of fathoms, he obtained the required charge in pounds of powder. In this manner he composed tables, serving to determine the quantity of powder required to charge a mine of the above form, when the line of least resistance is given. Belidor proposes a way of using these tables, as a means of obtaining much more extensive effects than those for which they are exclusively calculated. He supposes that the earth, upon the explosion of a mine, is compressed to an equal distance in every direction from the centre of the charge; and to the extent so acted upon by the ignited mass, he gives the name of a globe of compression. He considers the line drawn from the centre of the charge to the edge of the crater, which is the hypothenuse of a right-angled triangle, having the line of least resistance, and the semidiameter of the crater for the other two sides, as the radius of the globe of compression. Then, he says, globes of compression, like all other globes, are to each other as the cubes of their diameters or of their radii. If, therefore, instead of a crater whose diameter is equal to only twice the line of least resistance, (as estimated in De Valière's tables,) it be required to form one in which the diameter shall bear a higher ratio to that line, it is only necessary to add together the squares of the line of least resistance in the tables and the semidiameter of the crater, to obtain the square of the hypothenuse of that triangle: or, in other words, the square of the radius of the globe of compression which would be formed with the charge in the tables corresponding to that line of least resistance. Find in the same manner the square of the radius of the required globe; extract the square root from each; then cube them; and, by proportion, the cube of the former radius is to that of the latter, as the charge in the tables is to that, which would be required to produce a mine having the given dimensions.

The practical application of the rules above given, and indeed of any others as yet proposed, is however very limited; the effect produced in different soils by fired gunpowder bearing no constant proportion to the amount of the charge, and the error becoming very considerable when the charge is great. Experience also has shown that no quantity of powder will make a crater larger in diameter than about six times the line of least resistance; and that the diameter of the globe of compression in that case will not exceed about eight

* But a much preferable machine, resembling the hydrostatic bellows, with a very simple and convenient apparatus of pipes, has been introduced for the same purpose into the British service.

times that line. The case would be different, and effects would be always nearly in proportion with the magnitude of the charge, were it possible that the whole of the powder should become ignited at the same instant: this, however, cannot occur, as its particles ignite successively, and the portion first fired blowing up the earth above it, allows a certain quantity to escape through the fissures, either unfired or without producing any useful effect. The rule given by Belidor for determining the charge of a mine where the maximum of the effects of powder is required to be produced, the line of least resistance being given, is this: multiply that line, in feet, by 300, and the produce will be the required charge in pounds of powder. But the quantity of powder, thus obtained, much exceeds that which would have resulted from the employment of the formula before stated. The magnitudes of mines are now commonly expressed by the number of times the line of least resistance is contained in the diameter of the crater: thus a mine is said to be one lined, two lined, three lined, &c. according as the said line is equal to once, twice, three times, &c. the diameter; and from experiments recently made in this Country it has been determined that, in earth of medium tenacity, the charge, in pounds, may be found by multiplying the cube of the line of least resistance, in feet, by 0.033 for a one lined mine, by 0.095 for a two lined mine, by 0.21 for a three lined mine, &c.; and these numbers are nearly proportional to the squares of the diameters of the craters, when the lines of least resistance are equal. It has been also found that, when it is intended to destroy a solid mass of masonry by placing powder within it, the charge in pounds should be equal to about one-tenth of the line of least resistance.

The charge being ascertained, the chamber is excavated of the required dimensions, and a box of a cubical shape is prepared for containing the powder. If the ground be at all damp, it is necessary to calk and tar this box, the size of which must be such as to contain, as exactly as possible, the proposed charge. This, as well as the size of the chamber, may be determined by considering that a box, of which the capacity is equal to one cubic foot, will contain 57.6 pounds of powder. With respect to shape, the spherical would be better for the purpose than the cubical for obvious reasons; but the difficulty of making spherical boxes renders it necessary to adhere to the other form. The foot cube, abovementioned, is the inside dimension. If, therefore, for instance, it were required to make a box to contain a charge for four hundred and sixty pounds, it is evident that its interior capacity must be equal to eight cubic feet, or that the box must measure two feet every way on the inside. Inch planks will suffice for the timber of the box. Every thing being ready for charging the mine, the box is placed in the chamber, and being firmly fixed, a wooden trough reaching to its centre is introduced into it, through a square hole made for the purpose in the side next the branch. This trough is destined to contain the canvass powder-pipe or hose, by which the fire is communicated to the charge. The size of the trough should be about an inch square inside. With respect to length, it is continued as far as the spot where the fire is to be communicated, and it is made with such bends and angles as may be necessary. When the box is fixed and the trough is adjusted, the latter is nailed to the ground-sills of the branch frames to secure it from any movement. The

See fig. 7. plate iv.

powder-hose is then laid in it, with its end in the centre of the box, and with a peg driven through it to prevent the possibility of its recoiling. The lid of the trough is now nailed down, and covered with about one foot of earth, taking care at the same time to guard from damp or fire the outer extremity of the hose. This done, the powder of the charge is conveyed into the box in leathern bags, which the miners pass from one to the other, and which are emptied by the last into the box. When the latter is full, the lid is fastened down, and any vacant space about the box is filled up with sand-bags and rubbish strongly rammed. There is then placed up, against the box and the space thus filled, (as shown in fig. 6, which represents a vertical section through the branch and chamber,) a partition of strong planks firmly butted against the opposite side of the branch, where other planks have been put to strengthen the abutment. The interval between the bracing beams is filled up with sand-bags, and every thing which comes to hand; this wadding up or tamping, as it is called, is continued in the branch to a length equal to once and a half the line of least resistance; without which the mine might partly vent itself in that direction.

Now the greatest inconvenience experienced in the use of mines arises from the smoke of the powder, which, after the explosion has taken place, penetrates into the branch and neighbouring galleries, corrupting the already stagnant air even to endangering the lives of those who breathe it; in consequence of which the men are compelled to abandon the galleries until, by means of a ventilator,* the air may have been renovated. This has besides the evil of affording the enemy time to dig in the crater and reach the tamping or wadding of the branch without running any risk, since his work is performed in the open air, where a free circulation carries off the deleterious matter. Many have been the means at different times suggested for diminishing this evil: we shall however confine ourselves to that which has been most successful, and which was invented by the Commandant of the military school of Verdun, M. de Rugy. The greatest part of the smoke at the moment of explosion is projected outwards with the earth removed; another portion, which has been unable thus to escape, issues out after the explosion through the rubbish which has fallen back into the crater; and, lastly, a third portion, driven to the bottom of the crater by the rubbish, and being unable to find vent upwards, pours through the trough and fills the branch or gallery. It is not therefore so much the smoke of the charge that is to be apprehended as that of the powder-hose used for springing the mine; the latter smoke being impelled with violence through the trough into the branch immediately after the explosion has taken place. The smoke thus produced by the hose is more than sufficient to prevent the miner from reaching the mouth of the trough, owing to its pestiferous qualities: it is moreover soon joined by that which comes from the explosion of the charge; and the whole united spreads itself through the galleries to an extent greater or less in proportion to the magnitude of the charge and compactness of the soil. It was therefore found necessary by M. de Rugy to abolish the use of the hose; and his contrivance is as follows. In the centre of a small chain he fastens some match, and at each extremity of the chain he ties a small cord or string of a length at

* For a description of this ventilator, see Belidor's Treatise on Mines.

Fortification.

least equal to that of the trough it will have to pass through. A double instead of a single trough is made to communicate with the charge; and the above chain and strings being laid in it, the lid is fastened down as before. When therefore it is necessary to spring the mine, the match tied to the chain is lighted; and by gradually pulling the string it is drawn over a spot close to the charge, where some loose powder has been strewed, the ignition of which will of course communicate the fire to the mine. The use of the string at the other end of the chain is to enable the latter to be drawn back again in the event of any thing preventing the explosion from taking effect, or of the chain hitching any where on its way. This contrivance has often been found in the highest degree successful: it preserves the branch altogether from smoke, when the tamping has been properly executed, and when care is taken after the springing of the mine to stop up the mouths of the troughs immediately with sand-bags. But it has one objection, which is the great nicety required in making the trough: the inside must be very smooth, the angular parts properly rounded off, and the joints well put together, so that nothing may impede the movement of the little chain. Notwithstanding such difficulties, there is no doubt that this method is preferable to any other, when it is, as is generally the case, desirable to make use of the gallery immediately after explosion.

Before we conclude the present chapter, it may not be inappropriate to mention some precautions which it is necessary to observe, in order to prevent accidents whilst preparing the mine. The men should be obliged to take off their shoes, for fear of the nails which they may have on them. The nails for fastening the lids should be of a different metal from that of which the hammer is made. The powder should be conveyed in leathern pouches instead of sand-bags: lest any grains should get strewed along the ground, and thus form a train which might be productive of the greatest disasters. It is likewise recommended that the sand-bags used for tamping should not be filled up to the top; but that a portion should be left empty, and that the bag be then tied as near the mouth as possible. This, as the soil will lay loose in the bag, will render the filling up of chinks infinitely more easy, and the tamping therefore more compact. Two or more mines placed near one another may, by springing simultaneously, produce an effect much greater than could be obtained from them when fired one after the other. It may therefore, in some cases, be desirable to effect this joint and simultaneous explosion; and the way to do it is simply to make the hoses of all the charges of equal lengths. If likewise it be wished that one mine shall spring before another, it is only necessary to shorten the hose communicating with it; but no diminution of length need be made to allow for the effects of bendings in the hose, as directed in the works of most French Authors on Mining. For recent experiments in this Country have proved that, so far from burning more slowly, as asserted by those Writers, a bent powder-hose fires with rather greater rapidity than a straight one of equal length. But the real difference in the rate of combustion is too small to require any allowance in practice.*

CHAPTER VI.

Casemates.

Proper situations for casemates.

Though it is probable that, during ages to come, few opportunities will occur for making great improvements in the construction of fortresses; and though there is reason to believe that the means of defending places will never again become equal to those which may be displayed in the attack; yet these considerations should not be allowed to discourage the efforts of military men to give a degree of strength to their works, beyond that which can be afforded by an exact adherence to the Systems already in use. Since whatever can prolong, but for a few days, the defence of a fortress may, in some circumstances, be productive of the most important consequences. With these views, therefore, besides the casemates or covered batteries in the tower-bastions and flanks of the body of the place, which have been described in the Second and Third Systems of Vauban, such batteries have occasionally been formed or proposed in other situations, to cooperate with the artillery on the ramparts for the defence of ditches. It is plain, indeed, that casemated batteries, if confined to their ancient site in the flanks of bastions, must be utterly useless in any other constructions than the Systems above mentioned: since they would be masked by the tenaille which, by covering the curtain and flanks themselves from being breached, serves too important a purpose to be removed. But suggestions for a more general adaptation of casemates have, since the publication of the Systems of Montalembert and Carnot, been offered by French engineers; and it appears that some efforts to reduce these ideas to practice were, during the reign of Napoleon, actually made in the fortifications erected in Italy and at other extremities of the Empire.

Proposals of modern French engineers.

According to the author of the *Analyse de l'Ouvrage intitulé Réflexions Critiques sur l'Art Moderne de Fortifier*, these expedients consisted chiefly in the formation of casemated batteries within the ramparts of fortresses; and in the affording of a more effectual defence to covert-ways, with security against the ricochet fire of the enemy, by means of loop-holed galleries. On the faces of bastions or ravelins, where it is of importance to direct a powerful fire upon the works of the enemy, it was proposed to raise the rampart to a considerable height: but this, instead of being a mere mass of earth, was to consist of two or more tiers of strong and well-ventilated casemates; formed with masonry along the whole face; and having embrasures in the manner of port-holes towards the front. Each tier of casemates was to recede from that below it, according to the nature of the exterior slope of the rampart: so that, though the lower tier should be ruined by the enemy's artillery, the upper would not fall until the side walls should be demolished far within the face of the work. Behind these casemates it was proposed to have a vaulted gallery for the passage of guns, ammunition, &c., under cover along the rampart; and, on the opposite side of the gallery, to have other casemates for troops, stores, &c. Into these, also, was to be finally withdrawn the artillery of the anterior casemates; so that the fire might from thence be continued even after the latter should be destroyed. Over

* Almost all the details which belong to the processes of Military Mining, have during the last fifteen years, been very much simplified and improved by long practice and repeated experiments, at the school for the instruction of the officers and soldiers of the British Engineer Corps, under Colonel Pasley at Chatham. But the publication of the notes and rules compiled for the service of that admirable establishment has very properly been interdicted; and in preparing the portion of the present Article which relates to Mining, it has therefore been resolved rather to abstain from referring specifically to these latest improvements in the Art, than to make an unauthorized use of the official papers in which they are described.

Fortification.

the upper tier of casemates it was recommended that there should be constructed an ordinary parapet, from whence a fire of musketry and grenades might be directed to the bottom of the ditch. These different tiers of guns would permit the defenders to make a grazing or plunging fire on the approaches of the besiegers, as circumstances might require, and to oppose a quantity at least equal to that which could be brought against them. The artillery, also, being under cover, the effects of enfilade and reverse fires would be rendered null: so as to reduce the enemy to the necessity of employing only those which are direct, or perpendicular to the face of the work; and in the casemates the troops might be securely lodged close to the spots at which their services would be required. The partition walls of the casemates were to be loop-holed, and the gallery of communication secured by barriers at intervals; in order that, in the event of a breach being made in the face of a work, it might be defended on each side by a close fire of musketry from thence; and the Author of the *Analyse* concludes that it would be impossible to assault a place fortified in this manner, until after the whole of one face had been completely destroyed.

Nothwithstanding the benefits acknowledged to be derived from the covert-way, by the facilities which it affords to the communications about the works, many serious objections have been urged against it, chiefly on the ground of its exposure to the ricochet, which the traverses very imperfectly prevent: while the steep counterscarp has also been considered as objectionable; by reason of the impediment which it creates to the free movements of troops, when it may be necessary to send them from the body of the place to any part of the covert-way menaced by the enemy. On these accounts some modern engineers have proposed to dispense entirely with the covert-way, substituting for the counterscarp an inclined plane gently descending to the level of the bottom of the ditch; and even those who advocate the preservation of the covert-way, have recommended a formation of this part of the works different in some respects from that which has been hitherto practised.

Description of Napoleon's fortress of Alessandria.

The particular kind of covert-way here alluded to was executed before the works at Alessandria in Italy; a place which, during the reign of Napoleon, was fortified according to a plan given by General Chasseloup de Laubât. Alessandria is situated between the rivers Bormida and Tanaro, which, permitting inundations to be formed, render it in a great degree inaccessible. The town itself, which is of an irregular form, was surrounded by an enceinte consisting of bastions and curtains, but without ravelins. The ancient citadel, however, which was hexagonal, had those outworks; its bastions were constructed with orillons; and both these and the ravelins were covered with counterguards. About the whole, and surrounded by the waters, were disposed nine horn or crown works, each consisting of two or more bastions, but without ravelins; a covert-way and glacis extended along the counterscarp of the ditch; and, beyond these, was an advanced lunette retrenched by a redoubt and protected by its own covert-way. All these covert-ways were without traverses; but, for the purpose of concentrating a great quantity of fire on the capitals, the interior of the glacis on the longer branches was cut *en cremaillère*. The re-entering and salient places of arms were retrenched by redoubts; and those in the latter were of a polygonal form, and having the crest of the glacis carried round them parallel to each face: by which construction several advantages were obtained. For, the fires might be directed at pleasure with considerable efficacy, to any required part of the sectoral space about each place of arms, and might command in reverse the approaches of the enemy towards the re-entering works: while the same places of arms might be powerfully defended by the crossing fires from the latter; and the redoubts themselves (which, from their situation, were not liable to mask the fires from the principal works) were intended, by their elevation, to prevent the ricochet fire of the enemy from taking effect on the branches of the covert-way. Palisades, which have been hitherto considered as indispensable for protection against a sudden assault of the enemy, were here omitted: it being considered that the covert-way would without them be sufficiently defended by loop-holed galleries, which were formed for the purpose behind the escarps of the interior works. These costly and extensive fortifications were subsequently destroyed by the Austrian Government.

PART IV.

DESCRIPTION OF THE OPERATIONS OF A MODERN SIEGE; WITH RESPECT BOTH TO THE ATTACK AND DEFENCE.

CHAPTER I.

Progress of the Modern Art of Attack.

A general outline of the manner in which the Ancients attacked and defended their fortresses has already been given; and it may be observed that nearly the same processes continued to be employed, until the invention and use of cannon caused a thorough revolution in the Art of Sieges. We shall now endeavour, as well as our limits will permit, to follow the subsequent course of improvement in the methods of attack, down to the present times; and it will form the chief object of this rapid sketch, to trace the means by which the superiority, anciently experienced and until a late period preserved, in the resources of defence, seems at length to have been completely and irrecoverably reversed.

Long retention of the ancient course of attack.

During the XIVth and XVth Centuries, as the walls of ancient fortresses had for the most part undergone no alteration, and were consequently discoverable to their very bases from a great distance, little more was necessary than to establish batteries at four or five hundred yards from the place, and to employ them in breaching: whilst a trench was dug in a zig-zag direction towards the broken part of the rampart, in order to serve as a covered road for the troops in rushing to the assault. This mode of attack is practised even at pre-

Fortification. sent, when the walls of a place are considerably exposed. But when, by an improved disposition of the defensive works, and a due regulation of their reliefs, the walls were nearly hidden from the sight of the besiegers, the latter were of necessity compelled to bring their guns to the very counterscarp, in order to see the wall low enough down for effecting a practicable breach. The defence now gained an advantage over the attack; but it was merely momentary. The Art of gunnery made great progress towards perfection; and, when employed in the attack of fortresses, nothing is now found capable of resisting the overwhelming force of the modern artillery. Up to about the middle of the XVIth Century, no regular system of conducting the trenches, by which the fortifications were approached, seems to have been followed; neither were sufficient precautions taken for protecting the saps in proportion as they advanced. It therefore followed that considerable loss of time and of men's lives resulted to the besiegers from the success which attended the sorties from the garrison: who continually harassed the heads of the saps both by day and night, driving the workmen from the unfinished trenches, filling in the excavations, setting fire to the gabions, &c., and carrying off the intrenching tools. At the siege of Thionville, A. D. 1558, Montluc* assumes great credit to himself for having first suggested the means of obviating this evil: he tells us that he made at the end of each zig-zag a little offset trench to the right or left, and placed troops in it to fire upon any sorties that might attempt to disturb the workmen at the head of the sap. But this expedient was long employed in too limited a degree to prevent the frequent recurrence of such interruptions: until, at the siege of Maestricht, A. D. 1673, Vauban being fully empowered to conduct the attack according to his own judgment, abandoned altogether the old routine; and taking, it is said, a hint from the operations of the Turks before Candia,—where being compelled to advance with the utmost circumspection over a vigorously disputed ground, the Ottoman engineers had covered their advance with trenches in every direction—he traced his zig-zags across the three capitals of the front selected for the attack, and supported them at proper intervals by places of arms or trenches of sufficient extent to envelope the whole of the works against which his approaches were conducted.

Invention of places of arms in the trenches; of parallels; and of ricochet fires.

Hitherto the batteries of the besiegers had been thrown up in directions parallel to the line of rampart, the artillery of which they were destined to silence by a direct fire. The accomplishment of this end was, therefore, slow and difficult: as the assailants were under the disadvantage of opposing breastworks of loose soil to the well-settled parapets of the fortress. The only means which they had of silencing or dismounting the artillery of the place was by bringing down the parapets by the mass, and thereby depriving the guns of cover. But before this effect could be produced, their own batteries were repeatedly levelled; and hence sieges were of much longer duration and attended with far greater waste of lives, than after the introduction of a new mode of placing the siege batteries: of which we are now to give some account. It was at the siege of Philipbourg, A. D. 1688, that Vauban, who had for some time fully observed the disadvantage of placing the artillery in the manner above mentioned, determined to try the effect of erecting his batteries at right angles with the prolongations of the faces of the works; and of so regulating the charge and elevation of his guns, that the shot should sweep the whole length of the rampart with frequent bounds, dismounting the guns, and compelling the defenders to quit the parapet. This mode of firing, which is called *à ricochet*, was found very successful. *On ne chargeoit les pièces de ces batteries qu'à demi charge*, says the Journal of the siege, *ou à un quart de charge; et on les pointoit tout le long du chemin couvert des branches de l'ouvrage à corne et de celui à couronne. Les boulets, en effleurant les palissades et labourant la terre, faisoient plusieurs bonds; et alloient se perdre, en sautant jusque dans les chemins couverts et dans les ouvrages détachés du corps de place sur le front de la grande attaque. Ces sortes de batteries ont plus incommodé les ennemis que toutes les autres.* A few years afterwards, at the siege of Ath, (A. D. 1697,) the advantage of this new mode of firing was more fully seen, and its success more complete: for that fortress, of Vauban's own construction and regarded as his master-piece, was besieged and captured by him, after only thirteen days of open trenches, and with the trifling loss of two officers and fifty men killed, eight officers and one hundred and forty-two men wounded. The total expense incurred in the siege amounted to no more than £3570. The Art of Defence may be said to have never recovered from the inferiority, into which it fell in consequence of this change in the employment of the artillery. From this period we may date the decided superiority of the Attack; and there is little hazard in predicting that this superiority will even yet increase: unless expedients be found for covering the artillery of fortresses from the destructive ricochet, and the no less destructive fire of mortars; of which the use is now so much multiplied, and the service conducted with such astonishing precision.

CHAPTER II.

Preparations for a Siege.

Investment.

When the siege of a place is decided upon, the first step taken is to make the investment: which consists in seizing suddenly upon all the avenues to the place; carrying off every one and every thing which, by the negligence of the garrison, may be found outside the walls; and cutting off all communication with the exterior. The works of the place and the surrounding country are then carefully reconnoitred; and a correct plan made of them, if the besiegers indeed should not be already provided with one. The besieging corps are encamped beyond the range of the cannon of the fortress, in situations best adapted to the troops of each particular arm.

Lines of circumvallation and contervallation. See plate iii. fig. 1.

Lines of circumvallation and countervallation to cover these encampments are now so little resorted to, that we shall confine ourselves to the mere explanation of their nature; and it is here sufficient to observe that, generally speaking, they may be omitted in sieges, and a few forts or redoubts substituted for them in commanding situations. In modern warfare, each of these lines consists of a chain of redans, lunettes, or other works constructed at small distances from each other round the fortress, and generally connected by curtains either straight or broken. Lines of circumvallation are those which, facing towards the country, are intended as

* *Commentaires de Montluc*, lib. iv. ad A. D. 1558.

a cover from the attempts of the enemy's movable forces to disturb the operations of attack and relieve the place; and lines of countervallation are made within the above, at a convenient distance facing the fortress, to check the enterprises of a strong and spirited garrison. The finest example that can be cited of the utility of these lines, is the successful defence made by Cæsar within his intrenchments before Alesia, although attacked in front and rear by two armies, each more numerous than his own. But the suppression of these lines simplifies considerably the operations of a siege; though it would be imprudent to proscribe them altogether: since cases may arise to render their employment an unavoidable measure. Thus, at the siege of Mantua in Napoleon's first Italian campaigns, the French army was intrenched between works facing both the place and the country: its numerical weakness and other causes rendered the precaution necessary, and the result fully justified it.

Collection of materials.

Previous to commencing the attack, care is taken to provide in the neighbouring woods or forests the materials necessary for the construction of the trenches; *viz.* fascines, gabions, pickets, sap-faggots, and hurdles. Fascines are bundles about a foot in diameter, composed of the smaller branches of trees, bound together at intervals with twigs. They are of different kinds: the smallest are six feet long, and are used for tracing out the trenches on the ground; the larger kinds, which are frequently called *saucissons,* are twelve feet or eighteen feet long, and serve to revet the slopes of batteries. Gabions are cylindrical baskets open at both ends: the stakes, round which the twigs are woven, being allowed to project a few inches beyond the basket-work at both ends; so that, in placing them, the undermost ends are driven into the ground, and on the uppermost may be fastened fascines to augment the height and solidity of the work. The gabions used in sieges are rather smaller than those employed in other field works: they are here generally about eighteen inches wide and two feet and a half high, and weigh from thirty to thirty-five pounds. Pickets are made three feet long and sharp at one end. Three of these were deemed necessary per fascine. Sap-faggots are bundles of strong branches placed very close together, strongly tied in two places; and then sawed to a length of about thirty inches. The diameter of a faggot is from eight to ten inches; and a picket or stake three feet long is placed in the middle for the purpose of fixing it upright wherever it may be necessary. These faggots were used to close up the interval between two contiguous gabions; but sand-bags are now preferred for this purpose. The hurdles are woven on eight stakes, which form the skeleton. Their dimensions are usually six feet by three. Besides the above-mentioned stores, a quantity of sand-bags are prepared beforehand by the engineer department, and are filled at the moment they are required for crowning the parapets, or for other purposes. All those stores are accumulated in one or more places conveniently situated with respect to the attacks, and which are called the depôts. The judicious choice of the spots to be occupied by the artillery and engineer parks is by no means unimportant. They should be so situated as to permit ready and easy communications between them and the trenches. They should be near water for the convenience of the cattle, and as much as possible screened by distance or rising ground from the fire of the garrison.

In now proceeding to describe the operations of the siege, we shall suppose them to be conducted against a place fortified in Vauban's original manner; and that the front of attack consists merely of two bastions and an intervening ravelin. This supposition is made for two reasons: 1st, because it is the simplest way by which a general idea of the manner of conducting sieges can be conveyed; and 2dly, because there are more fortresses in existence constructed upon Vauban's First System than upon any other outline. We shall likewise, in order to avoid intricacies altogether foreign to our object, suppose the ground over which the operations are carried on to be a level plain. These preliminaries being settled, it will be proper, previously to breaking ground, to state what measures should be taken within a fortress, when threatened with a siege.

Precautionary duties of a Governor.

If the siege of a place is one of the most important operations in war and requires the greatest possible talent in the Generals intrusted with its conduct, it may easily be conceived that, to resist a well-conducted siege, requires still greater ability, experience, and cool intrepidity. Some imperfect idea of the duties involved in the defence of a place, may perhaps be formed from the following details.

An officer who is sent to take the command of a fortress, is bound to make himself acquainted with every circumstance essential to its defence. 1st, He reconnoitres personally all the ground over which an enemy may conduct his approaches; and weighs the advantages and disadvantages of each spot, so that he may act accordingly at a fit moment, and profit by every favourable opportunity of making sorties. 2dly, He carefully examines the advantages and defects of all the fortifications, in order to turn the former to the best account, and remedy the latter as far as may be possible. 3dly, He makes the necessary requisitions for completing the garrison in stores of every description, and endeavours to have an adequate number of troops of the different arms. 4thly, He prepares a proper distribution of his artillery, and causes tables to be made of the distances of all the points about the place. 5thly, From the moment at which the fortress is declared to be in a state of siege, both his powers and duties acquire new extent: the civil authorities are subordinate to him; secret intelligence and espionage without; a severe police within; civil and military administrations, finances, the works of the defence, the service of the artillery, the distribution of the troops, the employment of the inhabitants in extinguishing conflagrations, and the means of repressing popular commotions; all these important cares are his. The issue and expenditure of provisions and ammunition demand the strictest attention in order to prevent abuses arising from negligence or cupidity. And it is likewise important to keep the state of the provisions a profound secret previous to, and during the siege, for reasons too obvious to require mentioning.

Meanwhile the parapets, banquettes, platforms of guns, &c. are repaired; every thing is done to facilitate communication with the outworks; great quantities of fascines, gabions, and sand-bags are made and laid in store. The inundations, where ground permits them, are also now formed. Telegraphs may be constructed, and signals concerted. Every object within one thousand or one thousand two hundred yards of the place, that could afford cover to the enemy, is levelled with the ground; and every possible difficulty is opposed to the completion of the investment. Detachments of expert marksmen are stationed in ambuscade by day and night, as far as six hundred yards from the place, to cut off any

Fortification.

persons employed in reconnoitring. Whilst the besiegers are encamping and marking their first dispositions, every attempt is made to penetrate their views as to the front which they mean to attack. Care is taken to watch from the church steeples where they appear to be fixing their park of artillery: that once ascertained, the rest can be nearly guessed. From this moment a sufficient proportion of cannon is concentrated upon the front attacked; and the service of the garrison is organized: it is divided into three bodies, one of which reposes, another remains in readiness to act, and the third is on immediate duty. The measures to be taken by the Governor of a place might of themselves fill volumes: but we have said as much as our limits justify; and we will therefore proceed to the operations of the besiegers.

CHAPTER III.

Operations of a Siege.

Attack.

Every thing being in readiness for breaking ground, a working party, regulated in respect of numbers according to the extent of the intended parallel and communications, parades at night-fall at the depôt. These men are provided with intrenching tools (spades and pick-axes) and fascines. They are marched to the ground, preceded by an armed force, called the covering party. When they have reached the spot where the engineers have previously marked out (with a white line) the place for the first parallel and the zig-zags, or oblique trenches, communicating from it to the depôt, they are extended along that line, at intervals from each other of six feet, which are marked out for them by the non-commissioned officers. Each workman then lies down upon his belly, to be the less exposed to the fire of the garrison whilst waiting for orders to begin to dig. In the mean while the covering party, drawn up at a convenient distance in front of the parallel, after detaching small parties nearer towards the place to give early intimation of sorties, is likewise ordered to lie down. Every thing being thus arranged, the word is given to begin to work: upon which the men loosen the earth with the utmost possible expedition; throwing it up on the side next the place; and taking care to leave one foot of space between the edge of their excavation and the tracing line. This is to prevent the earth from crumbling into the trench, and the space so left is called the berm. As soon as day begins to dawn, or sooner if the parallel be capable of affording cover, the covering party is withdrawn from its exposed situation into it. Should any light-balls be thrown from the town amidst the workmen, they will endeavour as soon as possible to extinguish them, either by shovelling earth upon them, or covering them with tubs made from commissariat casks sawed in two, a few of which ought to be kept in the depôt ready for the purpose. For a general idea of the dimensions and appearance of parallels, and zig-zags of communication, we refer the reader to fig. 3 and 4. pl. iii., which represent profiles of such works.

Defence.

Meanwhile a good look out from the fortress is kept throughout the day to ascertain where the enemy proposes breaking ground; and as soon as night sets in, light-balls are thrown in every direction to a distance of six hundred yards from the place. From the moment the enemy's design is discovered, the heaviest possible fire is made upon his workmen from the cannon of the place. This may perhaps scare more than do harm: but it will not fail to intimidate the workmen; and a sortie performed rapidly and cleverly by a few dragoons, will, together with the darkness of the night, which magnifies danger, tend to create confusion and delay the progress of the work. There being no longer any doubt as to the front which the enemy has chosen, the works of the defence will forthwith commence accordingly. Traverses will be placed along the terrepleins of the faces, and parados—or covers from reverse fires—on the flanks. Interior retrenchments (if none permanently exist) will be commenced in the bastions and ravelin. Tambours will be made in the re-entering places of arms of the covert-way, and a double palisade on the latter extending along the whole front of attack. If these two last measures be properly taken, it will be out of the enemy's power to possess himself of the covert-way otherwise than by the regular sap; as no hope will remain of his succeeding in attempting it by storm. If the ravelin be a full one, that is, if its terreplein be on a level with that of the rampart, the retrenchment made in it may be in the form of a small ravelin with flanks. But if it be a hollow one, no other retrenchment can be made than a strong tambour of carpentry, with loop-holes in it, covering the communication or retreat in rear. The retrenchments in the bastions, if the latter are full, (and if they are not, it is needless to think of retrenching them,) may be made in the form of a tenaille; or, if there is room, in the form of a small front of fortification extending from shoulder to shoulder, or rather from points on the faces taken at a few yards from the shoulders. These retrenchments are made of earth, revetted with saucissons, and armed with palisades and fraises. Field-pieces and howitzers are brought into the projecting parts of the covert-way to ricocheter the besieger's works. Mortars are placed at the gorges of the bastions, along the curtain and in the ravelins. They may even be placed with advantage in the ditch, when it is a dry one.

Attack.

The oblique communications towards the place now commence; and are driven forward from the first parallel to the intended site of the second. The prolongations of the faces of the works and branches of the covert-way are marked on the first parallel, in order to determine the situations of the ricochet batteries: these batteries, and the particular faces of the bastions and ravelins which are enfiladed by their fire, may be seen in fig. 2. The time occupied in their construction is generally from forty to fifty hours. Two or three large mortars are placed in each of these batteries, to throw shells into the works; by means of which the besieged is kept in continual alarm, and can nowhere find safe cover. It must not be supposed that there is any absolute necessity for fixing the ricochet batteries exactly in the first parallel: they may be planted in any convenient situation upon the prolongations of the works; and it will be attended with no great disadvantage if that situation be not so near the place as the first parallel. At the sieges of Ypres, Fribourg, Mons, Namur, Maestricht, and Gibraltar, they were of necessity constructed at one thousand or one thousand two hundred yards from the works of the place; and they produced, notwithstanding, a very good effect. Recent experiments have, however, shown that the shot from such batteries are most efficacious, when the distance of the latter from the work to be enfiladed does not exceed four hundred yards.

Fortification.

Defence.

Light-balls are thrown out from the fortress to enable the gunners to see and fire upon the ricochet batteries whilst constructing; and it may be expedient, in order to retard their completion, to batter one or two of them at a time with a good number of cannon, as, for the reason to be presently given, the besiegers prefer delaying to unmask their batteries until they are all finished and ready to open their fire. If the enemy's guard in the trenches does not appear to be very strong, a grand sortie may be tried. If the case be otherwise, small ones may answer the purpose by frightening away the workmen occasionally, and thus causing their operations to be suspended.

Attack.

The ricochet batteries are finished and unmasked; and the line of aim, the charge, and the elevation of each gun are regulated with such a nicety, that they shall be able to fire by night as well as by day. The unmasking of all the batteries is done at one moment; in order that no particular one should draw upon it an undue proportion of the fire of the garrison, whereby it would soon be utterly destroyed. The communications to the second parallel are continued; but the nearer the place is approached, the greater is the vigilance which should be exercised to anticipate the sorties of the garrison.

Defence.

The utmost diligence is now observed in forwarding the works of the defence. The same fire of cannon and mortars is kept up as in the preceding days. The capitals continue to be ricochetted and sorties are undertaken at appropriate moments.

Attack.

The effect of the ricochet batteries is already visible from the diminution of the fire of the place; so that the second parallel may be undertaken at three hundred yards from the crest of the covert-way. The second parallel is to be executed by night, under the protection of troops stationed in short trenches, which are driven out from the angles of the zig-zags, towards the right or left hand, as the case may be; and as the distance from the place is now so much reduced that the fire of musketry and grape may here be fully felt, it is deemed necessary to use gabions for the construction of this parallel, in lieu of fascines: which gives to the profile of the trench, when finished, the appearance exhibited in fig. 3. The operation of digging the trench behind a row of gabions placed openly on the ground is called the flying sap. Some engineers recommend the constructing of a redoubt at each end of the parallel, as a more effectual prevention against being turned by sorties; but it is better to unite the extremities of the two parallels by a trench well defiladed from the place, as shown on the left-hand side of fig. 2.

Defence.

The construction of the second parallel is disputed by every possible means, and the most vivid fire of all arms is directed upon it. Small sorties are made during the night; and towards morning, when the guard of the trenches and the working party are much exhausted with fatigue, a grand sortie of fresh troops is poured out upon them. The firing at daybreak is continued as usual.

The second parallel is at length finished in spite of opposition. The communications forwards are commenced. New zig-zags are marked out and executed to within one hundred and twenty, or one hundred and fifty, yards of the covert-way. At this distance it is found necessary to give additional support to the works of approach; and half-parallels are made for the purpose. Batteries are made at the extremities of these demi-parallels, for containing howitzers wherewith to dismount the artillery of the flanks, sweep the branches of the covert-way, and destroy its palisades. The precautions taken for repelling the sorties will depend upon the energy exhibited by the garrison at this period; but it will be well always to keep on each flank of the trenches, and covered by a breastwork of sufficient height, a body of cavalry ready to cut off the retreat of the enemy, should his zeal lead him far enough in attacking the trenches.

Defence.

In the defence, the same line of conduct is followed as before, counteracting as much as possible every thing done by the besieger. The means of resistance are diligently improved. The damaged parapets are repaired; as are likewise the traverses, palisades, bridges, ramps, &c. that may have received injury from shot or shells.

Attack.

The batteries in the demi-parallels are finished, and their fire is opened. Zig-zags are pushed forward along the capitals. These zig-zags now necessarily become shorter, more frequent, and more oblique, in order to adhere to the condition of avoiding the enfilade fire of the place. The flying sap is no longer practicable; it being impossible, under so close a fire from the covert-way and ramparts, to place the gabions in the uncovered manner hitherto done. A slower but safer expedient is now adopted, called the full or single sap. Its execution, according to the latest practice, is as follows. The sappers employed are told off in brigades of four; and these are numbered first, second, third, and fourth. The first sapper rolls before him a large gabion stuffed full of fascines, to cover him whilst he places a gabion in the line of the intended trench, and fills it by excavating a portion eighteen inches in width and as much in depth. The second sapper, who follows him, widens the trench to three feet two inches without increasing the depth, and continues filling the gabions. The third sapper increases the depth of the trench to three feet, on a breadth of twenty inches, under the part excavated by the second sapper; so that there is left a step eighteen inches in breadth and as much in height on the side of the trench which is next to the line of gabions. The fourth sapper only increases the breadth of the trench by ten inches, but he digs to the depth of three feet from the ground: thus the work of the four men is nearly equal; and cover is more speedily obtained than by the former method of executing this species of sap. When the gabions are full, saucissons are fastened on the top of them to render the work more solid; and the trench is then carried to the necessary breadth by the ordinary working parties of the line. The work of the sap is of so dangerous a nature, that the sappers are frequently relieved; and their exertions are, moreover, stimulated by a pecuniary recompense, which is increased in proportion as the danger becomes greater. The average quantity of this kind of work which can be executed per diem of twenty-four hours is one hundred and sixty yards in length. When the zig-zags have reached the foot of the glacis, a sap is driven to the right and another to the left; and this being done at the head of each zig-zag, the junction of these saps and the extension of the outside ones, as far as to embrace the whole front, will complete the third parallel.

Defence.

This is the most favourable moment for making vigorous sorties, by issuing suddenly from all the branches of the covert-way; to facilitate which, ladders may be placed along the covert-way to enable the troops to pass over the parapet. Every expedient, which the most

Fortification. intelligent genius and intrepid spirit can devise, must be tried to delay the junction of the saps which are to complete the third parallel: for, from the moment that this is effected, all attempts at sorties from any part of the front attacked will be hopeless. A heavy fire of grape is directed upon the heads of the sap.

Attack. As soon as the third parallel is completed, batteries are commenced in it for howitzers, great mortars, and those for throwing stones or one pound balls, wherewith to drive the enemy from the places of arms in the covert-way. By this means all the fire of the place that would obstruct the crowning of the covert-way will be subdued. The batteries in the first parallel may now cease firing, being replaced by those last mentioned. When circumstances render it expedient to storm the covert-way, steps are made in the third parallel on each side of the capitals of the bastion or ravelin attacked, that the troops may be enabled, with greater facility, to pass over the breastwork of the parallel when rushing to the assault. These steps occupy a sufficient length for a company to go over in line. The cases are rare where such a mode of attack is justifiable. The loss which always attends it is incredible. In the attack which we have supposed, it could not be undertaken with the least prospect of success, if the covert-way has been provided with a double palisade. The alternative, therefore, which remains, is the attack of the covert-way by a continuation of the former process. From the third parallel, at thirty yards from each side of the capitals, curvilinear saps are driven forward in such a manner that when they join, they shall form an arc towards the place about sixteen yards beyond the third parallel. (See fig. 2.) From the centre of this circular portion, a double sap is driven straight along the capital to within about thirty-six yards of the crest of the covert-way. This double sap now branches off into two single ones, to the right and left, for the formation of what are termed trench-cavaliers,* or excavations having very elevated parapets, with a view of obtaining a commanding fire of musketry into the covert-way, and driving from it any troops who might dispute its crowning. The reason why this distance is chosen for the trench-cavaliers is, that they may be constructed beyond the range of hand-grenades, which can generally be thrown to about twenty-six yards. The defenders of the covert-way being thus driven from the space comprised between the two foremost traverses, the besiegers hasten to sap up to the salient angle, and then extend their lodgement to the right and left along the whole crest of the covert-way, which the enemy will be obliged to abandon in proportion as the sap advances. The batteries destined to extinguish any remaining fire in the defences are now commenced at the salient angles of the covert-way; (See fig. 2.) these are called counter-batteries. The breaching batteries are likewise undertaken, as is also the descent into the ditch.

Defence. The heaviest possible fire of every kind is kept up upon the heads of saps, and particularly upon the trench-cavaliers whilst constructing. A few oblique embrasures may advantageously be opened in the curtain for this purpose, the effect of which will be greater, owing to the difficulty of ricochetting the guns placed there. Barrels of inflamed combustibles may also be rolled down the glacis upon the heads of saps. When by the crowning of the covert-way, the latter is abandoned, care is taken to destroy the traverses in it, that they may not afford cover to the enemy; and this may be done by exploding some small charges previously lodged in them for the purpose. The enemy's descent into the ditch is anticipated; and oblique embrasures are made at the extremity of the curtain to pour a fire into the opening, which he is about to make into the ditch through the counterscarp wall.

Attack. As soon as the batteries on the crest of the glacis are ready, they begin their work of counter-battering and breaching. Expert marksmen are placed all along the lodgement, to pick off the enemy's gunners, or any one in fact whose head is seen above the parapets or through the embrasures. The descent and opening into the ditch is completed; and a sap is made across the latter (if it be dry) to the foot of the breach. If the ditch is wet, a bridge is made across it by an accumulation of fascines. Now, if the works within were known not to be retrenched, the assault might forthwith be given, should the garrison, upon being summoned, refuse to capitulate; but as the besieged is supposed to have retrenched himself, the sap must be continued up the breach, when the latter has been made quite practicable.

Defence. Meanwhile the sap across the ditch is heavily battered by the besieged. Dispositions are made for an obstinate defence of the breaches, by lining their tops with abattis strongly linked, or by chevaux de frise of sword-blades kept in readiness to be linked together the moment the enemy ceases to fire upon the breach. This was executed by the French at Badajos,* with a success that will be long remembered. Loaded shells are kept ready to roll down upon the assailants, as well as barrels of combustibles. A large fire may be lighted on the breach, and kept up by a continual supply of fascines steeped in pitch or grease. The foremost troops destined to receive the shock of the assailants, are provided besides their ordinary arms with all possible weapons of resistance; and when obliged to cede to the overpowering torrent of fresh assailants, they effect a retreat in good order to their retrenchments; behind which they renew the defence.

Attack. If the ravelin is only retrenched by a tambour at the gorge, the assault may be given at all three breaches simultaneously. As soon as the storming party have cleared the top of the breach, sappers are brought forward to make a lodgement on it with gabions, which has been fancifully called the magpie's nest. Howitzers are then brought into this lodgement to answer the fire of the retrenchment; upon which likewise a heavy fire of shells is directed from the batteries on the crest of the glacis. The interior of the bastion is crossed by the sap in the usual manner; the counterscarp of the retrenchment is crowned with batteries by which the parapet is to be destroyed; and, this being effected, the assault is given.

Such are the usual operations in the attack of an ordinary fortress; and such likewise is the defence when a proper resistance is made. The hope of protracting the latter beyond this period must depend almost entirely upon the feeling and spirit of the inhabitants. The siege of Saragossa† in the Peninsular War presented a memorable example of a defence continued, from street

* A hint for raising these works was taken from the practice to which the Turks, at the siege of Candia, were obliged to resort to gain a plunging fire into the bastion of S. André, the fire of which they, until then, had been unable to get under.

* On the night of the 6th of April, 1812.

† *Rel. des Siéges de Saragosse et de Tortose*, by General Baron Rogniat, Paris, 1814.

to street, for twenty-three days after the whole of the works of the place had been penetrated. But such instances of patriotism are so rare, that they are rather to be admired than anticipated. The siege which we have been supposing, would occupy upon a fair calculation nineteen or twenty days, from the first day of breaking ground.

Protraction of the defence by salient outworks.

When a place is fortified with very salient outworks, it becomes convenient to direct the central line of approach on the capital of a bastion, and the others on those of the two collateral ravelins, for the reasons which have been formerly given. The process of the attack will, however, be the same as that above described, so far as the completion of the third parallel: but the sapping must afterwards be conducted only up the glacis of each ravelin where, at the salient angle of its crest, counter-batteries are formed as before; the approaches on the glacis of the intermediate bastion being suspended on account of the reverse fires from the ravelin on each side. Before the construction of the breaching batteries on the glacis of the ravelin, it may be necessary to execute a portion of a fourth parallel in the direction of a line joining the extremity of the counter-battery on each ravelin, and extending about midway from thence to the salients of the bastion: in order to afford cover for bodies of troops, who may keep down the fire from the works, and protect the sappers in forming the breaching batteries which are to act against the ravelins. These latter works being breached, may be assaulted, and a lodgement may be formed about half way up each of the breaches, where it will not be exposed to the fire of the redoubt in the ravelin. A trench is next driven by full sap from the lodgement to the counterscarp of the redoubt; and, turning to the right and left, the sappers extend this trench to about the middle of the face of each ravelin. In this excavation, if space permits, artillery may be placed to breach the redoubt: but should the narrowness of the ravelin prevent the formation of such a battery, either a portion of the mass of the ravelin must be destroyed by a mine, and the redoubt breached, through the opening thus made, by a battery purposely constructed on the glacis; or a miner may be attached to the escarp of the redoubt, where, under cover of timbers placed on end and leaning against the wall, he may make an entrance and place powder in chambers formed under the capital of the work. This being fired, a breach will be made in the redoubt, by which an assault may be given. Should it succeed, the interior of the work will be occupied by a lodgement of the besiegers; from which a fire of artillery may be directed both against the opposite curtain, and against those flanks of the collateral bastions which have a view of the intended descent into the main ditch. Since this redoubt commands the ravelin in which it is placed, the defenders will be obliged to abandon any retrenchments which they may have made in the latter; and, subsequently, the redoubts in the re-entering places of arms, which are also commanded by the ravelins. The outworks being now in possession of the besiegers, and there being consequently no reverse fires to annoy them, the approaches on the intermediate bastion may be commenced by sapping up its glacis, and crowning it with breaching and counter-batteries as before; but under the protection of the troops in the fourth parallel, which is completed for the purpose by driving a portion from the extremities of the counter-batteries to join the part already executed. A place thus fortified may reasonably be expected to hold out seven days longer than one constructed on Vauban's First System.

CHAPTER IV.

Subterranean Attack and Defence.

Management and effects of a system of countermines.

In the preceding detail of the ordinary processes of a siege, we have purposely omitted all reference to the use of mines either by the assailants or the garrison: because, as such works cannot in every case be employed; and as they form rather occasional aids than component and indispensable parts of the hostile operations; it has seemed useless to interrupt the general narrative of the attack and defence above ground, and to distract the attention of the reader, by intermingling with the main subject any unconnected notices of subterranean warfare. Moreover, this method of assailment constitutes so distinct a branch of the Art of Sieges, as well to deserve a separate consideration; and the present appearing the most appropriate place wherein to introduce also some explanation relative to the management and effects of the system of defensive mines, of which we have, in a former Part, already described the nature and construction; we shall devote the Chapter before us exclusively to a brief sketch of the subterranean operations, to which both the assailants and defenders of a fortress may have recourse in order to accelerate or retard its capture. And here it may at the outset be observed, that the success of either party will greatly depend upon the latitude given by the other to his efforts, either through impotence of means, or want of equal address and intelligence.

Defence.

If a fortress has been beforehand provided with such a regular system of countermines as we have already described, the advantage of preparation for a subterraneous conflict should, with proper energy, lie wholly on the side of the besieged. As soon as his enemy, by breaking ground, has indicated the front of attack, he should drive forward branches to meet him from the ends of the listening galleries even so far as the points at which the demi-parallels are made, with a view of commencing the work of destruction as far off from the place as possible. It is likewise recommended to sink shafts at the ends of the listening galleries, from the bottoms of which other galleries may be driven towards one another so as to form by their junction a second envelope, which may intersect the line of the besieger's approaches in whatever way it may be directed. For then, on hearing him at work, either from this new envelope, or from the ends of the above-mentioned branches which have been driven forward, he may soon be reached, and smothered by a small charge sufficient to blow in the wall of the gallery behind him, yet not great enough to produce a crater. For it is obviously disadvantageous to the besieged that his mines should produce any craters if he can possibly manage otherwise; since they become so many places of cover where the enemy can immediately make lodgements. But if a crater is inevitable, it should be made of the largest possible size, as, by reason of its shallowness in proportion to its width, it can be more readily seen into from the place, and consequently will afford less cover. The besieged having his work all ready need do no more than listen attentively; hearing without being heard; announcing himself only by effects

as prompt as destructive; and rendering it as difficult to escape from, as to reach him.

Attack.

Let it now be supposed that the besieger has begun by sinking shafts behind the parapet of his parallel, at forty yards from the ends of the branches of the besieged; and that, in order to avoid destroying his own works upon the surface, he intends advancing twenty-six or twenty-seven yards before he charges his globe of compression. Then since miners, as already explained, can be heard at work as far off as thirty yards, it is evident that the besieger, as soon as he shall have driven about ten yards of gallery, must excavate the remaining sixteen or seventeen in the hearing of his enemy. From the moment the latter has heard him, he drives forward without loss of time, in a parallel direction, a branch sixteen or seventeen yards long, which will of course extend beyond that of the besieger by two or three yards: so that the latter may be immediately taken in reverse, and smothered by a charge calculated to destroy a good portion of his gallery. Here it may be seen that the besieged can, if he takes care, be always beforehand with the besieger, the nature of whose work is calculated to occupy much more time than that of his enemy; for he has to excavate a large chamber, lodge a great quantity of powder, (transported thither by night for greater security from accident,) and tamp a great length of branch. Now the best thing which the besieger can do, in this case, from the moment that he may have reason to apprehend that the besieged has got into his rear, is to stop short immediately and charge his globe of compression: the springing of which, although perhaps rather premature, may nevertheless crush the besieged in his new works, as well as blow in his galleries of earlier construction. The miner of the besieger, however, may avoid by a timely retreat the destruction preparing for him: as he can easily distinguish that his enemy is tamping and not driving, by the difference of sound, which in the former case recedes, and in the latter draws nearer.

The disadvantages which may result to the besieger from thus prematurely springing his first globes of compression are as follows: 1st, The too great proximity of his own trenches on the surface may entail their destruction. 2dly, By his not being perhaps sufficiently near the ends of the branches of the besieged, neither the latter nor the envelope will be much damaged. 3dly, He will not have made the desired degree of progress. Immediately after the springing of the first globes of compression, the besieged will go to the ends of those parts of the branches which may have escaped destruction, and drive forward in order to lodge charges under the borders of the craters. This will easily be done, as the springing of the globe of compression will have produced no bad smell in the broken galleries; and he will have the start of the besieger, who has to make a lodgement on the borders of the crater before he can even commence sinking his shaft. This lodgement may therefore be repeatedly destroyed by the besieged, if the sinking of the shaft be made on the border of the crater; and the shaft may as often be choked up by the earth being blown into it, if it should be sunk from the bottom of the funnel The besieger will have to surmount this difficulty after the springing of each of his series of globes, in advancing towards the place. Hence it may be conceived what labour, danger, and loss a well-countermined glacis must occasion to the besiegers; and the advantage in favour of the besieged is probably not overrated in a computation that the delays resulting from all the chicaneries of a well-managed subterraneous defence are capable of adding two months to the duration of a siege. Such is the estimate of Bousmard, who supports his opinion by citing the example of the siege of Schweidnitz by the Prussians in 1762; and to this may here be added the more memorable siege of Saragossa, in the last Peninsular War, the long defence of which, even after the fall of the fortifications themselves, was chiefly owing to the multitude of mines sprung in the very streets.

System of fougasses.

Besides the regular systems of mines described in the foregoing pages, there is a more expeditious method of employing the same kind of means in the defence, although upon a diminutive scale. And this is by a system of fougasses, which can be made even when the time is too short to allow of establishing galleries. It consists in burying under the parts of the surface which are most likely to be attacked, well calked and tarred boxes or even barrels full of powder; and laying in a trench, which is afterwards filled up, the troughs destined to convey the fire to the charges, either all at once or successively. The troughs extend even to within the works, in order to facilitate the springing of these expeditiously constructed mines; to ensure the success of which, the following precautions ought to be taken. See fig. 21, plate v.

1st, If the hole in which the powder is to be lodged is at all damp, it will be well to make it still deeper, and then fill up the bottom to the required height with loose stones. This will enable the water, if there be any, to filter down to the bottom. 2dly, The troughs must be laid at a depth of six feet, at least, underneath the surface, to prevent their being disarranged by the fall of shells; and if more than one trough is to be laid in the same trench, they must be separated by at least a foot of well-trodden earth, so that the first which may be fired may not shake or disarrange the other. 3dly, Care must be taken in refilling the shafts* and trenches to plough up the whole of the surface equally, so that nothing shall indicate to the enemy the situation of the trenches and charges. 4thly, The ends of the troughs and hose must reach to such places within the works as shall secure them from sudden attacks, and enable them to be sprung with the utmost coolness at the most favourable moments. It will not suffice for the security of these mines that their troughs terminate behind the banquette of the covert-way: they must be carried through the counterscarp to be fired at the bottom of the ditch. Otherwise the enemy, by assaulting the covert-way, might discover and tear up all these troughs, and utterly prevent their being employed against him, when he establishes his lodgement on the crest of the glacis. The boxes should be placed so as to destroy the double saps along the capital, the trench-cavaliers, the crowning or lodgement on the crest of the glacis, and the breaching batteries. They may likewise advantageously be sunken in dry ditches, both of the outworks and body of the place, at spots at which it is most likely that breaches may be made. Their troughs must be conducted to the gorges of the outworks or behind the tenaille, or wherever they may be fired with security. Those likewise which may be employed for the defence of the breach, or are placed in the terrepleins of the works, must have the ends of their troughs within the redoubts or retrenchments. Each trough must be marked

* In the present case these are usually called wells.

with the number that distinguishes the box to which it communicates; and the exact place of the latter is correctly laid down on a plan of the works, so that the springing may be regulated as occasion shall dictate.

Fougasses are likewise an excellent means of demolishing any flêche, redoubt, retrenchment, traverse, or any other temporary work which having, until its capture, been of service to the defenders, has then ceased to be so, and may even be of advantage to the enemy into whose hands it has fallen. The facility and economy of a system of fougasses, and the similarity of effects produced by them with those of regular mines, might, at first sight, induce a preference to be given to them. But it must be remembered that though such means may be successful against an enemy unable to employ mines himself, they are altogether insufficient and even null against a besieger who has it in his power to do so. For ceasing to advance upon the surface, beyond the influence of the fougasses, he may drive galleries as far as he pleases; and not only blow in the counterscarp but at the same time tear up the troughs without giving an opportunity of disputing one inch of ground by their means. It must not, however, be concluded from this that the employment of these boxes of powder should be proscribed in the defence of places: they may, on the contrary, often be appropriately used, conjointly with regular mines. And if judiciously managed, this mixture may lead the besieger into a serious error, by making him mistake their explosion for that of the regular mines, and either induce him to take precautions entailing useless labour, loss of time and powder, or lull him into a security which may afford the defenders opportunities to put in execution more powerful means of destruction. Fortification.

PART V.

FIELD FORTIFICATION.

CHAPTER I.

General Principles of this Branch of the Art.

Under the term of Field Fortification, in contradistinction from the Art of constructing, defending, and assailing Permanent Fortresses, is usually comprehended the whole business of disposing and preparing such temporary works, and improving such natural advantages of the ground, as may assist and support the operations of an army in the field, and enable it partially to impede, or totally to prevent, the advance of an enemy, though in superior force. In Field Fortification, therefore, every expedient is good, which effectually conduces to arrest or retard the progress of an adversary. In this, perhaps, more than in any other branch of the profession, is the engineer enabled to display his intelligence: here few restrictions shackle his inventive genius; the opportunities of displaying it are frequent; and the materials are commonly abundant. Not so in Permanent Fortification: where the rarity of the occasions which present themselves for the formation of new works discourages that devotion to the subject which is necessary to the attainment of excellence; and where the vast expense of the constructions operates as a serious check to the adoption of even the most meritorious suggestions.

It would be an endless undertaking to enumerate the multitude of objects, which may be classed under this division of the Military Art. With regard to works thrown up in a plain open country, certain principles and certain rules deduced from experience may be laid down; but for the greater part the intelligence of the individual must be his sole guide in the judicious application and use of the means and materials which circumstances may place at his disposal. Barren, indeed, must be that country which offers none to second a discerning officer in the task allotted him. A farm-house, a mill, or a Church surrounded by walls, may with very little expense be converted into an excellent military post, by loop-holing the walls, barricading the entrances, or erecting traverses or portions of parapets in those places which offer a good flanking fire; or, in a word, by turning to account every means of resistance which may present itself.

With regard to those Field-works for which, as we have said, certain rules may be observed, it will be sufficient briefly to show that, although in magnitude and importance they are inferior to the works which constitute permanent fortifications, nevertheless the general rules which govern the construction of the latter are in a great measure applicable to the former. In the first place, the immediate object of both is equally to procure cover from the assailant's fire, and to place between him and the defender an obstacle which he must overcome. These ends are obtained by excavating a ditch, and throwing up the earth to form a parapet or covering mass. The impossibility of carrying about with an army any implements of construction beyond the mere pickaxe and spade, naturally imposes limits to the magnitude of the works; and therefore the maximum of height that it is found possible with these simple means to give to the crest of the covering mass is twelve feet. And the same dimensions, twelve feet, must be considered the maximum for the depth of the ditch; this being the greatest depth from which a man can throw up the earth to those who are employed above in giving to the mass its requisite shape.

The reader will find represented in fig. 1, plate v. a portion of the parapet and ditch of a Field-work of the most common profile: that is with a mere command of seven feet and a half; and we proceed to give the nomenclature of its various parts, together with their uses, in order that the contents of the following pages may the more readily be comprehended. A B is the height of the parapet: a dimension which will depend upon the nature of the surrounding country; as it is necessary that the interior of the work should be entirely covered from the view of the enemy. B C is the thickness of the parapet; and this must be regulated according to the nature of the attack to which the work may be liable: for instance, if only exposed, by its situation, to an infantry attack, three feet will suffice; if the enemy Plate v. fig. 1.

Fortification.

can bring artillery against it, but have only six-pounders in his Field train, the thickness of the parapets may be safely restricted to six feet; if nine-pounders to nine feet; and if twelve-pounders to twelve feet. For experiments have shown that at a short range a musket-ball will penetrate into well-beaten ordinary soil about eleven inches; a six-pound shot, four feet; a nine-pound shot, six feet; and a twelve-pound shot, ten feet. We have not here reckoned upon a greater caliber than twelve-pounders, because eighteen-pounders and twenty-four-pounders are never used in the Field; although the former have very lately been considered a part of our Field train. The height of the ordinary race of men being considered as constant, the distance of the banquette *a b* below the crest A is made equal to four feet or four feet and a half, to enable the troops to fire conveniently over the parapet. The base of the slope of the banquette is generally made equal to twice its height *a c*; and its breadth (*a b*) is usually three feet. A level space H L, of about eighteen inches in breadth, called a berm, is left between the foot of the exterior slope of the parapet and the escarp of the ditch, for the purposes mentioned below.

The superior slope A I of the parapet is directed so that the enemy may be discovered from head to foot when upon the edge E of the counterscarp: this slope must be considered as an evil in one respect, for it is evident that, if the upper surface were horizontal, the parapet would be much stronger. To preserve therefore to the crest A an adequate strength, the maximum depression of this slope is fixed at one-sixth of its breadth; and this limits in some measure the height of the parapet. The interior slope A *b* is also an unvarying quantity: its horizontal breadth is made equal to one foot and a half to give it a strictly sufficient solidity, and at the same time to enable the troops to approach the parapet conveniently when firing. The exterior slope I H varies with the nature of the soil; but in ordinary cases it forms an angle of about 45° with the horizon. I is called the exterior crest of the parapet; A the inner crest or covering line. The berm H L ought not to be made wider than one foot and a half, lest it should offer too great a facility to the escalade; it might therefore appear advisable to dispense with it altogether, but it is too useful in the construction of the parapet to allow of being suppressed. Moreover it prevents the rolling down of the earth; removes to a greater distance the pressure of the covering mass; and thereby contributes to the solidity of the work. This berm, usually constructed upon the natural level of the soil, ought, in every case, to be at least six feet lower than the interior crest to prevent the enemy from seeing into the work when he may have reached the berm. The slopes both of the escarp L N and counterscarp M O must vary with the soil, with the means employed to support them, and with the intended duration of the work. The breadth and depth of the ditch will vary according to the thickness and height of the covering mass. When a covering mass is thrown up without either banquette or superior slope, it is called an *epaulement.*

The reader being thus acquainted with the nature of covering usually obtained in Field-works, we may proceed, first, to describe the plan or outline of such works; next, to touch upon the details of construction; and, ultimately, to point out the means whereby defences of a temporary nature may be strengthened or rendered more difficult of capture.

CHAPTER II.

Single Field-works.

The redan. See fig. 2.

Of all the works which an engineer may be called upon to construct during a campaign, the most inconsiderable is the *redan.* This work is open in rear; and is therefore only employed to form part of a line of works destined to cover a camp, to defend the avenues to a village, dike, bridge, or defile, &c. Its principal defects, considered as a single work, are that its ditch is without defence; and this defect it has in common with most works of a mere temporary nature. Besides, as it is invariably found that soldiers when placed behind a parapet will fire directly before them, that is, at right angles to the parapet, it follows that there is a large undefended sector in front of every redan. This may in a measure be remedied by cutting off the salient angle with what the French call a *pan coupé:* that is, a portion of the parapet having its crest perpendicular to the capital of the work. There is no stated rule for fixing the length of face of a redan: though that which is usually given to it is fifty yards. The redan when thrown out in front of other works to increase their strength receives the name of *flèche.*

The lunette. See fig. 3.

The *lunette* or *bastion* is a work rather more considerable than the redan, being composed of two faces and two flanks. Its object is to enclose more advantageously the interior space, and permit a more direct fire upon the sides. The lunette being, as well as the redan, open in rear, is employed only in cases similar to those for which a redan would be constructed. This work is of very common use, owing to its simplicity, facility of execution, and easy adaptation to any ground. There is nothing arbitrary in its form and dimensions, which must be determined by local circumstances: but in ordinary cases and on level ground, its faces may be fixed at sixty yards long, and its flanks at ten. The defects of the lunette are the same as those of the redan.

Bonnet de prêtre. See fig. 4.

The French engineers give the name of *bonnet de prêtre* to two redans so connected as to afford a mutual defence. It therefore consists of two faces A B, C D, and of two flanks A E, E C, usually shorter than the faces. This work being likewise unclosed in rear, its application must be subjected to the same restrictions as in the case of the two former: it is generally employed to cover a bridge, and its faces are then defended by batteries placed on the opposite banks of the river. The bonnet de prêtre is a more efficient work than the lunette, as its salients are better defended; it has no dead sector in front, but the ditches of the faces are unflanked. The construction of this work may be regulated as follows. Make the line of the gorge B D equal to one hundred yards, and the capital I K equal to fifty; at right angles with I K set off I A, I C each equal to twenty yards; set off I E also equal to twenty yards; join the flanks A E, C E, and faces A B, C D. The angles A and C will by this construction be equal to 72° 30′, and therefore will exceed the minimum prescribed for such angles: it being a rule in fortification, both permanent and temporary, that salient, that is, projecting angles, shall never be made of a smaller opening than 60°. The angle A E C will be a right angle whereby the best possible defence is afforded to the salients A and C: it being likewise a rule in fortification that a line which flanks another shall make with it, at least, an angle of 90°; and this is in consequence of the incorrigible habit which is found in soldiers of

Fortification.

firing perpendicularly to their parapet, in spite of all the care which can be taken to make them direct their fire upon any particular point.

The redoubt. See fig.

The redoubt is an enclosed work without flanks, and is usually made of a quadrilateral form. On a flat even country the redoubt is generally made square; there being no reason why one face should be made longer than another, or one angle greater than another. But on a varied surface, it is necessary to adapt the shape to the nature of the country. An opening is left in the middle of one of the sides for communicating with the exterior; and a traverse is thrown up within, to prevent the enemy from seeing into it. The quadrilateral redoubt is defective; inasmuch as the dead sectors in front of its angles favour the enemy's attacks upon four different points, and weaken the defence by dividing the resistance of the garrison. Endeavours have been made to correct this defect by giving to the redoubt a circular form; but this is only substituting one evil in lieu of another. A circular redoubt would with equal developement of parapet circumscribe a greater space, and in this point of view is advantageous: but its application to the ground is difficult; its figure makes the resistance on all sides equal; and the distribution of its fires prevents any particular side (which may be most liable to attack) from receiving an adequate proportion of defence, at the same time that it affords a greater fire than necessary upon other points of difficult access. The angular redoubt, on the contrary, may have its principal faces directed against the points most important to be defended; it is besides, more easily executed and applied to uneven surfaces. The deadness of the angles may in a measure be remedied by the expedient suggested for the redan, that is, by making a pan coupé of six or eight yards in length. The size of a redoubt is always proportioned to the garrison which it is destined to contain. For lining the parapets, the calculation is that each soldier occupies three feet of front. The interior free habitable space is regulated by the consideration, that a square fathom should be allowed for every four men. By interior free space is understood that comprised within the foot of the slopes of the banquettes. In the largest sized redoubts the free habitable space will always be sufficient for the convenience of the garrisons usually thrown into them; and the smaller ones, being seldom occupied, excepting in moments of actual resistance, it is of little importance—provided they have sufficient men for the effective lining of their parapets—whether the habitable space, as it is called, be equal to that above prescribed. Nevertheless, all French authors have thought it necessary to lay great stress upon the mathematical accuracy with which the capacity of the work is adapted to the number of men who are to occupy it; and each has laid down some rule which he thinks preferable on this account to that of his predecessor. From the nature of the outline of a redoubt, it is almost needless to acquaint the reader that its ditches are without defence, or in other words, dead. The manner of palliating this evil will be shown in another part of this Essay.

Star forts.

The next enclosed work in order of importance is the star fort. This is constructed either upon a triangle or upon a square: in the first case it has six points, and in the latter eight. The hexagonal, or six pointed star fort, is constructed upon an equilateral triangle A B C of ninety yards length of side; by dividing each side into three equal parts, and describing on the centre one an equilateral triangle D E F. By this arrangement the salient E is defended by the fire of the lines A D and B F; and the points A, B receive a similar defence from the faces D E and E F: so that the defect of dead sectors is much diminished, if not totally removed. This star fort is a little defective in its flanking: for the re-entering angles being obtuse, the fire from F is not directed precisely upon E, and we have already stated how difficult it is to induce troops to fire obliquely. The entrance $m\ n$ is made in a re-entering part, being there less exposed to attack, as it is further removed from the enemy and protected by a cross fire.

See fig. 6.

See fig. 7.

The star fort with eight points is constructed upon a square, the sides of which may be ninety yards long. Each of the sides is divided into three equal parts; and upon the central one is described an equilateral triangle. In this, as in the last-mentioned work, the salients are but obliquely flanked: but this defect is not so sensibly felt as to render it necessary to resort to constructions foreign to the simplicity indispensable in Field-works, which it is almost always required to trace out expeditiously, and often with the aid of no other instrument than a correct eye. Most of those minute perfections, to which so much consequence is attached by mere theorists, and which are perceptible only on paper, would not prolong the defence of a work one single minute. It can scarcely be too often repeated that it is necessary in Field Fortification to avoid that spirit of minutiæ, which is too apt to lose sight of greater objects in running into details of little or no importance. Four of the points of this octagonal fort are less acute, and therefore more solid than those of the former work: but a more real advantage, and one which ought to obtain for it a decided preference over the latter, is that with equal length of parapet its interior space is greater.

Bastion forts, or Field forts. See fig. 8.

The bastion fort considered as a Field-work should be constructed only upon the square or pentagon. The distance between the points of the bastions, or in other words, the exterior side A B of the polygon, may vary in length between one hundred and two hundred yards, which allows of great latitude and facility for the application of this kind of work to almost every site. The reason why A B cannot be made shorter than the minimum above prescribed, is, that owing to the relief of the works, the ditches near the centre of the curtain would not be discoverable from the parapets, and would consequently be dead: besides, the flanks would dwindle into insignificance. The range of common muskets also requires that the extent A B of the front should not exceed the above maximum; for it is an axiom that "lines, which have to defend a salient point, must not be further removed from it than will enable the musketry to range beyond that point, and to take effect upon the enemy before he reaches it."

Star and bastion forts, and particularly the latter, are employed in fortifying important posts. Their construction ought to be of a solidity approaching to that of mixed fortifications; which, though not revetted with masonry like permanent works, are nevertheless intended to last several campaigns. These forts will not only serve as posts of importance, but are also useful as depôts for stores of every description, for which their spaciousness renders them fully eligible. They should therefore be so well conditioned as to apprehend nothing from sudden assaults, but should compel the enemy to break ground before them. A Field-work which is honoured with a formal attack, or which compels the enemy to resort to more than ordinary means for its

Fortification. reduction, is justly deserving of celebrity; and we need not hesitate, notwithstanding the inherent defects in their construction, to class with the latter, our redoubts at Toulon, the gallant defence of which, in the Revolutionary War, gained so much honour for the British arms.

CHAPTER III.

Continued Lines.

Lines. Several works placed in succession parallel to, or surrounding, a position, generally receive the name of lines. There are two kinds of lines; continued lines and lines with intervals. Continued lines consist of an uninterrupted range of parapet. Lines with intervals are formed of isolated works—whether open at the gorge or enclosed —placed at convenient distances from each other, and affording a mutual flanking defence. Continued lines are mostly employed where a pass is to be closed. And lines with intervals where it is intended to oppose resistance to a vigorous attack: because the detached works which compose them may be more carefully constructed and better defended; serving as strong points round which the troops may manœuvre; and thus combining, whilst on the defensive, all those moral advantages of the offensive which result from the feeling of superiority. Hence continued lines are best adapted to frontier defences, and lines with intervals to camps and fields of battle: nevertheless, the preference ought always to be given to that, which can be soonest prepared, and defended with fewest troops.

Continued Lines: with redans; The different modes of constructing continued lines are as follows: with redans, tenailles, cremaillères, or bastions. Vauban, in his *lines with redans*, placed the latter at distances of two hundred and forty yards from centre to centre. This is at present considered too great a distance; and it has been proposed to place them at one hundred and eighty yards, by which the faces of the redans will mutually derive a nearer defence. This is, however, at best, but a weak line; and the frequency of its employment in war can only have proceeded from the readiness with which it can be constructed. Another way of improving upon Vauban's outline is by breaking the curtain B D into a very obtuse redan B C D. With this alteration the works assume the name of *queue d'hironde*, or *swallow-tail lines*. This construction, although better than that with redans, is nevertheless far from being good: for, although the parts of the line between the redans are defended by the fires from the faces of the latter, yet upon an equal developement of parapet the queue d'hironde line presents three salient points, whereas the redan line has only two; and as the points project equally towards the front, they are all liable to be attacked at the same time. The curtains, also, of Vauban's line, are less exposed to the ricochet fire, than the branches of the swallow-tailed construction. The salients are the principal points of attack, because they are closer to the enemy; and because they have sectorial spaces in front of them undefended by direct fires: while they are also easily enveloped by the enemy's converging fire. A means of correcting the defect arising from too many points of equal saliency, would be to carry forward the salient of the great redan B C D, making its faces perpendicular to those of the small ones: so that upon a line of one hundred and eighty yards only two points of attack would be offered; and the salients would moreover be well defended by flanking fires.

See fig. ' See fig. 10. See fig. 11.

with tenailles; The *tenaille line* is composed of redans of equal dimensions. Their capitals are usually seventy yards long, and their demigorges one hundred. There exists so great a similarity between this and the former outlines, that to specify the minute differences in their defensive properties, which writers on fortification have remarked and dwelt upon, would be to consume time to no purpose; and these lines are here described merely to complete the usual enumeration. One great fault common to them all, is, that their long branches are exposed to the enemy's enfilade fire; and in an open country this evil will be more sensibly felt in the tenaille line than in any other. See fig. 12.

with cremailleres. Lines *en cremaillère* are composed of a succession of faces and flanks perpendicular to one another. The faces may be made one hundred yards long, and the flanks twenty-five, still supposing them constructed upon a flat and open country: for, on an irregular surface, all the branches may vary considerably in length from the general dimensions; the most essential rule being that the works should conform to the shape of the ground, and have their salient points on eminences. The cremaillère line is superior to any other, for the purpose of uniting principal works placed at too great a distance for mutual defence. In this case the cremaillères ought to change their direction at the centre *a* of the line, whence there will result a good cross fire before the middle of the interval. See fig. 13.

The bastion line. If particular circumstances should make it requisite to give to a line a more than ordinary degree of strength, there is no doubt but the bastion outline ought to be preferred. Its principal advantage is that every part of the ditch is well seen into and flanked: but the salients have not all the defence which could be desired. There are certainly cross fires in front of them, but these scarcely range beyond the counterscarp and leave great open spaces X without any at all. This may, in a measure, be remedied by breaking the curtain, for then the fire of the half curtains directed upon those spaces X will render the access to the salients more difficult. The bastion line is more troublesome to construct than any other, owing to the quantity of earth which requires removing between the flanks and the curtain, when the counterscarp is directed, as in permanent fortification, to the shoulders of the bastions; and this may account for its not being oftener employed. It is evident that, if the counterscarp were traced, as in other works, in directions parallel to the faces, flanks, and curtain, the ditches of the faces would be unseen from the opposite flanks, the sight being obstructed by the mass of earth in front of the curtain. When there is not sufficient time for removing the entire mass—and it seldom happens that there is—the evil may be palliated by sloping away the earth in the direction of the line of fire drawn from the crest of the parapet of the flank to the foot of the ditch of the opposite face: whereby the ditch of the face will be perfectly laid open to the fire of the opposite flank. Some writers object to this remedy, as facilitating the descent of the enemy into the ditch: but it may be observed that the descent into the ditches of Field-works is in practice usually an easy matter; and those ditches should be regarded rather as excavations which have served to furnish earth for the covering masses, than in the light

See fig. 14. See fig. 15. See fig. 16.

Fortification.

of serious obstacles to the enemy's attacks. Besides, even though the facility of descent should be admitted to be of great advantage to the assailant, it is evident that in availing himself of the slopes here mentioned, he must expose himself to a reverse fire from the flank behind him, and this is not likely to augment his assurance.

The redan bastion line.

The line just described is applicable to any surface: but that which may next be mentioned having its various parts given in numbers, is unfit for irregular surfaces. It certainly appears, however, the best that can be used on an even country, where only a limited length of retrenchment is required; and though thus restricted in its application, some notice of it in this place is due to the inventor, Colonel Dufour, (Director of the Military Academy of Grave,) to whose excellent Work on Field Engineering the compilers of the present Article are bound to express their obligations. At each end of a side A B four hundred yards long, erect perpendiculars A P, B Q. Set off on the latter A D, B E, each equal to fifty yards, and D P, E Q each equal to thirty yards; join D and E; on D E take D G, E H, each equal to sixty yards, and bisect D E in C. Draw A G, B H, and produce those lines indefinitely; join C and P, C and Q, and make C M and C N each equal to A G or B H. Then, in order to obtain flanks sufficiently near the salients A, C, and B, to afford those points an adequate defence, let fall from G, M, N and H, perpendiculars G g, M *m*, &c. upon the lines of defence M P, A G, &c., and join the interior extremities *m*, *g*, &c. of the flanks, to form the curtains. This outline is superior in many respects to any of the former; but it is certainly rather too complicated, and is moreover inapplicable to every kind of surface: it can, therefore, be entitled to a preference over the common bastion line only in the circumstances already mentioned; and when these occur, its advantages are as follows. Suppose two fronts of fortification on the lines A C, and B C traced upon the usual principles, it will be found that the redan-bastions in fig. 17 are more spacious than the ordinary ones, and that the flank M *m* is longer in the former than its corresponding flank in the latter would be, which is strictly conformable to the principles of the Art as it has to defend the point of attack. G *g* indeed will be smaller, but this is attended with no inconvenience, since its fire is directed upon a point not much exposed. It may, however, be noticed as some defect, that the fire of the short flank G *g* when prolonged in a direct line would fall within the salient of the advanced bastion at B, and expose its defenders to the risk of injury from their own comrades.

See fig. 17.

CHAPTER IV.

Lines with Intervals; Têtes-de-pont, &c.

Lines with intervals.

Lines with intervals are composed of isolated works, such as redoubts or redans placed at certain distances asunder. In determining the situation of these works, it must be observed that the intervals between them should never be greater than two hundred yards; so that they may be able to defend one another by a crossing fire, at an efficient range. The outline of each work must also be so disposed that the faces which are to produce that crossing fire between two works, shall make with each other an angle not less than, nor much exceeding, a right angle. The military world has long been divided in opinion whether the preference should be given to continued lines, or to those with intervals. The former seem to have been held in highest estimation until after the commencement of the XVIIIth Century; for the greatest number of retrenchments made by the French and by their opponents during the reign of Louis XIV., and particularly during the Wars of the Succession, were continued lines. In our days this manner of retrenching armies is rejected; and when the nature of the country will admit of it, that of isolated works has the preference. Lines with intervals have over the other species of lines the following advantages. 1st. They are more easily applied to the ground, and made to occupy the points most essential for the defence; not being shackled by the conditions which must be observed in outlines where all the parts are connected together. 2dly, They require less labour, and consequently enable the engineer to give a greater degree of perfection to the works within a determined time, and with fewer workmen. 3dly, They require fewer troops for their defence, having a less developement, and thus allowing a greater force to be directed upon the most exposed points, or a greater number to be kept in reserve. 4thly, By this disposition the troops may with facility pass from the defensive to the offensive, and *vice versâ*, as may best suit the occasion: whereas, when lining a continuity of parapet, the same troops possess no advantages except such as may be derived from a judicious adaptation of the outline; and having no facility of issuing from behind their cover, are restricted to mere defensive operations, which are apt to produce an unfavourable effect upon the courage of the soldier. It may be remarked, in conclusion, that continued lines ought to be employed only in situations of moderate extent, where a small number of men being sufficient for their defence, a considerable portion of the army may be kept in reserve at points favourable for offensive movements.

Choice of positions.

In the choice of positions or situations for the encampment of an army, it is evident that elevated ground should always be preferred, when its extent is not disproportionate to the number of troops: in order to increase the difficulties of the attack, and permit the defenders to see the works and dispositions of the enemy while their own are wholly or partly concealed. A superiority of command, also, renders it possible to take advantage of any movement of the enemy by falling rapidly on his convoys or attacking his columns on their march. Positions are, however, often unavoidably taken up in a plain country; and it may be observed that no great inconvenience ensues from the occupation of such situations, provided they are protected by natural obstacles, or by works expressly constructed, and that by any means the enemy is prevented from approaching near enough to annoy the lines by his fire. But if the position should be commanded within range of artillery, the most disastrous consequences may be induced: for the troops being either exposed to heavy loss, or driven from their posts to obtain shelter behind woods or other cover against the enemy's fire, the works may be assaulted and carried before the defenders can be rallied from their confusion.

Whether in plains or on eminences, the approaches towards the ground occupied by the enemy should be well guarded by a chain of outposts, which must sur-

Fortification.

round the encampment within view of it and at the distance of about a mile from it in every direction: so that, on an alarm being given, there may be time for the troops in the lines to put themselves in a posture of defence. These outposts should be covered by woods, villages, or houses; or if no such cover exists, redans, as before described, must be constructed for their protection. Within the chain of outposts, and at two or three hundred paces from the encampment, redoubts or batteries must be formed: for the purpose of protecting the line by their crossing fires, and principally to secure the wings against any attempt of the enemy to turn them, or to get to the rear of the army, by which the supplies from its magazines, and its own retreat, should this become necessary, might be entirely cut off. The disposition of these works, next to the choice of the position, demands the serious attention of the engineer: since on it depends, in a great measure, the success of the army in maintaining its ground; and, consequently, the probability that the enemy may be compelled to retreat and leave the field free for the prosecution of offensive operations. When, therefore, the position is on an eminence affording a good view of the neighbouring country, and particularly of the avenues by which an enemy might approach, the redoubts should be constructed at intervals on the salient points in front of the line, where they may defend those avenues by direct and flanking fires from an artillery sufficiently numerous to prevent the enemy's columns from advancing without experiencing a serious loss. As the enemy may attack and attempt to storm some of these redoubts, they should evidently defend each other reciprocally, and be capable of making a powerful resistance in front. For this latter purpose they should be placed on the crests of the heights which they occupy: that they may be able to graze with musketry the descending ground about them; and if, from the steepness of the slope in any part, this should be impossible, collateral works should be constructed in situations where they may see and defend that part by which an enemy would otherwise advance unmolested against the principal work.

In general, the highest point in the line is the key of the position; and, as the retention of this is an object of the utmost importance, it should be occupied by a redoubt of the strongest kind. This point being a pivot about which the whole army manœuvres, it is plain that it should be situated about the centre of the line; but as, in some cases, it may happen to be in one of the wings, then additional precautions will be necessary to prevent it from being cut off from the other parts of the line: such as making good communications to it, by which succours may be sent in force when it is hard pressed by the enemy. Such communications should also be made when the divisions of an army are separated from each other by woods, marshes, or streams: passages should be cut through the first, and causeways or bridges formed over the others; in order that in every part of the encampment troops may be able (if possible out of the enemy's sight) to march to each other's support. Natural obstacles greatly increase the defensive properties of a position; and if there should be a river at the foot of any part of the eminence on which the army is situated, and near enough to be subject to the fire of the artillery, it would be impassable by the enemy and would completely protect that part of the line. It may be here observed that an army encamped possesses many advantages over the garrison of a fortress: for the degree of resistance that can be opposed by the latter is always known to the enemy, and the permanent nature of the works prevents the plan of operations from being changed; so that the enemy can regulate his dispositions accordingly. The case is different with an army in the field, which can vary its measures with the nature of the anticipated attack: either by opposing force to force, or by surprising the enemy; or by taking advantage of the localities to prevent his columns from acting together.

British lines covering Lisbon.

It may not be unsatisfactory to close this general description of lines of intrenchments with a short account from the invaluable Memoranda published by Colonel Jones,* of the works executed before Lisbon by British engineers, between the years 1809 and 1812, for the purpose of protecting that city and the meditated retreat of the army from Portugal. These celebrated works were enclosed redoubts disposed in two great chains crowning the heights which extend between the Atlantic Ocean and the Tagus: the first or exterior chain was situated about twenty miles North of Lisbon, or twenty-five miles North of Fort St. Julian, which forms the Southern extremity of the Peninsula, and was the proposed place of embarkation. This chain commenced at the point at which the Zizandra falls into the Atlantic; the works occupied the waving ridge of heights on the left bank of that river, and extended to about two miles west of Torres Vedras, terminating near the Western extremity of the Sierra de Monte Junto. At the mouth of the little river St. Lorenzo, about seven miles South of the Zizandra, the second or principal line of forts commenced; and these were constructed on all the salient points and eminences of the ridge of heights extending from the Sea to the Tagus, and passing close to Mafra, Montechique, and Bucellas; which lie successively Eastward of each other, and through which proceed three of the four great roads leading from the North to Lisbon. The fourth, or Eastern road, runs through Alhandra close to the Tagus. The whole country between the great roads is hilly and broken, and cannot be passed by an army with its artillery without much difficulty and delay; and, to secure the roads effectually on the principal ascents at the passes of Bucellas, Montechique, and Mafra, were constructed strong redoubts and batteries for artillery, so disposed as to enfilade the roads and concentrate their fire upon particular points of them, at which it was intended to form mines, deep cuts, or other artificial obstructions when they might be required. The ridge of Monte Graça was crowned by one large and several smaller works; and these, with the works at Torres Vedras, served as isolated outposts to the principal line just mentioned: blocking up the approaches, and giving time for the troops to occupy the line before they could be attacked in force. A chain of redoubts connected the works on Monte Graça with others forming part of the line, and situated on the ridge at Alhandra: to the South of this ridge the Tagus is not passable by an army; and therefore the works could not be turned by an enemy on the opposite side of the river. Along the North face of the ridge just mentioned, and near the summit, on an extent of two miles, there was cut an almost perpendicular scarp fifteen or eighteen feet high, every part of which was closely flanked by a covered musketry fire, and also by artillery in enclosed works constructed on the salient points of the heights: all the flanking works

* *Memoranda relative to the Lines thrown up to cover Lisbon in* 1810. By Colonel John T. Jones, Royal Engineers.

Fortification.

were plunged into by larger redoubts on commanding interior peaks. Additional redoubts were, subsequently, formed between the ridge at Alhandra and that of the Sierra de Serves at Bucellas; and the valley between them was blocked up by an abattis with a covered communication in its rear. The front of this communication could be swept by artillery from the Alhandra heights, and closely flanked by musketry from some stone buildings in the sides of the valley.

In the whole line between the Ocean and the Tagus there were one hundred and fifty-two redoubts mounting, in all, five hundred and thirty-four pieces of artillery, while the army to be covered consisted of but fifty thousand men; a small number when compared with the extent of the line, which was equal to about twenty-nine miles, and required above thirty-four thousand men to garrison the works. But this vast developement is, in the present case, justified by military men on the ground of the extraordinary strength of the principal works, which is considered as rendering them in some respects fortresses. Colonel Jones, moreover, observes that not more than one-third of the works would have been required to be fully manned at any one period. The redoubts were generally adapted to the ground, and were of every capacity: the smallest was constructed for fifty men and two pieces of artillery; others could contain five hundred men and six pieces, and the great redoubt on Monte Graça required one thousand men and had twenty-five pieces. Some of the works were in the shape of star-forts, but it was objected to these that the defence of the ditches was imperfect; and the direct fire towards the front was insufficient. It may lastly be observed that there was an enclosed work on the height between St. Julian and Oeyras, near the proposed point of embarkation, with independent redoubts and batteries: the principal work was well flanked and required a garrison of one thousand three hundred and forty men.

Têtes-de-pont.

Works thrown up in front of bridges to cover and defend them, constitute what are called *têtes-de-pont:* their general disposition and shape may vary in a thousand ways, according to the nature of the localities and to the importance of the object. The works constructed to serve as a tête-de-pont are frequently ill-adapted to this object: being either too small to cover the bridges properly from the enemy's fire; or having so great a developement that a large portion of the army is withdrawn from active service merely to guard them. A tête-de-pont ought to be capable of effectually concealing the bridge; but it should require for its defence the smallest possible number of troops, in order that the disposable forces may be so much the more numerous. When the passage is one of importance, it may be expedient to give to the tête-de-pont the form of a line with intervals: that is, upon an arc of a circle whose radius is one thousand or twelve hundred yards, a disposition should be made of redans or detached bastions, flanking each other; and, in rear of these, and covering the immediate approaches to the bridges, a central work should be placed: serving as a redoubt so disposed as to batter the intervals between the retrenchments in front, defend their gorges, and afford a safe retreat to the troops when driven from the advanced works. A disposition of this nature will keep the enemy's cannon at a sufficient distance from the bridges to prevent any annoyance in passing the river. If the tête-de-pont is constructed upon a re-entering bend of the river, the redans or bastions may be placed in a straight line or one nearly so, which would improve the defence and lessen the extent of works. In this case, also, the redoubt of the tête-de-pont may easily receive a flanking defence from batteries established on the opposite bank, or on islands which are frequently found in the bends of rivers; and it is considered that, on this account, and because the bridge is more effectually concealed from the view of the enemy, a re-entering bend or elbow, the concavity of which is on the enemy's side, is the most advantageous place for a tête-de-pont.

See fig. 18.

The advanced works should be made capable of containing about two hundred men; their gorges should be secured by a row of strong palisades; and they should be provided interiorly with a small redoubt or blockhouse. Lunettes constructed thus carefully, and well fraised and palisaded, may be placed at greater distances from each other than those of ordinary construction, because being stronger in themselves, they stand in less need of immediate succour: their salients may be placed three or four hundred yards apart. A system of works of this kind, partaking of the nature of mixed *fortification*, would be well adapted to cover an important passage of a river; and the enemy, unable to carry them by assault, would be compelled to go through the formalities of a siege. Indeed, without these conditions, the army, which may have retreated through the intervals to shelter itself from the enemy's superior forces, would have to cross over to the opposite bank, and abandon to feeble garrisons the defence of the advanced works. These garrisons, too weak for a long resistance, would now betake themselves to a retreat, if such a measure were still in their power; the approaches would therefore no longer be covered; and all the advantages of the têtes-de-pont would vanish at the first appearance of the enemy. It is therefore necessary, in order to oppose an effectual resistance to the progress of the enemy, that the exterior works should have all possible solidity and strength.

When a tête-de-pont has not the defensive qualities that could be desired, and the retreat of the army to the opposite bank is a measure of necessity, it may be effected in the following manner. The retreating army is divided into as many columns as there are intervals between the advanced works; each column takes the direction of its allotted interval, and when it has passed the latter it deploys immediately in rear of it. Those of the columns which have not room for deploying either as a first or second line, immediately cross over to the opposite bank. The fire of the works will open as soon the space in front of them is sufficiently unobstructed by the retreating army. The infantry deployed stands now alone before the enemy; the advanced works being evacuated, and their garrisons retiring through the intervals of the divisions. The artillery and cavalry, with the exception of a few guns and squadrons, have already passed over the bridges. The infantry commences its retreat *en échellon*. As soon as the central redoubt is unmasked, its fire is opened to protect the retreat. When the enemy is master of the field, the garrison of the redoubt retires; the victors now enter tumultuously in the abandoned work and hasten to get possession of the bridges; but they are stopped by the last tambours made of strong palisades, and defended by one or two companies of grenadiers, who have volunteered to dispute the spot until the bridges are destroyed. When their object is gained, these companies either surrender themselves prisoners, according as they may have re-

Fortification.

ceived instructions, or make their escape by swimming or by boats placed at hand for the purpose.

The redoubt, or central work of a tête-de-pont is an important part which ought not to be negligently constructed; since it immediately covers the passage, and ensures the retreat of the last defenders of the works in advance. The redoubt ought, therefore, to be made capable of offering the greatest possible obstacles to the attack. It usually consists of two or three bastion fronts; the wings being defended by batteries thrown up in rear on the opposite bank of the river. The passages are made in those wings: they should be about twenty yards wide, and masked by traverses thrown up within. Inside of these redoubts, others made of timber in the manner of tambours should be constructed to cover the immediate approach to each bridge: the utility of this measure must be apparent from the foregoing description of the manner of effecting the retreat. Care must likewise be taken when constructing a tête-de-pont, to throw up one or two batteries for destroying the bridges, in the event of the enemy's unexpectedly forcing the central work, and not giving time to cut them away or burn them. Fig. 18 represents a grand tête-de-pont, where all these conditions have been observed. It often happens that there is but one bridge to be covered; in this case the central work may be much smaller than the preceding one, and be composed of a single bastion front connected with the bank by long branches; or it may be a mere bonnet de prêtre, or even a lunette defended from the opposite side. These last two are most usually executed in petty warfare: but nothing can be fixed respecting their dimensions, both these and their shape being always determined by local circumstances.

CHAPTER V.

Details of Construction.

On the relief of field-works.

Having described the shape or outline of the principal works executed in the field, it will be necessary to say a few words respecting their relief, before we proceed to show the manner in which they are constructed. A good relief is not less essential to an intrenchment than a well-combined outline. The most usual height given to the covering masses of field-works is seven and a half feet: this height is chosen in order that a man on horseback may be unable to see over the parapets into the work. Parapets are nevertheless often made of less height: for instance, six feet is not a bad relief if there is no apprehension of a cavalry fire; and intrenchments constructed hastily to procure cover for a detachment, are often made no higher than four and a half feet: but in this case, as there would not be sufficient cover, it is necessary to excavate about one and a half on the inside. The required solidity of the work, as we have already said, depends upon the nature of the projectiles which it may have to resist. But whatever be the thickness of the parapets, it is necessary that the earth excavated from the ditches be sufficient for the formation of the covering mass. Whence it follows, that the breadth and depth of the ditches must vary with the height and thickness of the parapets. It may be well to repeat, that the means usually at hand for the construction of field works will not permit a greater depth to be given than twelve feet to the ditches; and, in order that the latter may be at all serviceable, they ought not to be less than six feet deep. Hence, in every field-work constructed solely with spade and pickaxe, the depth of the ditch will vary between six and twelve feet, and these dimensions may be considered as their limits. In calculating the depth and breadth of a ditch according to the dimensions of the profile of the covering mass, it must be remembered that the earth generally augments in volume when loosened from its natural bed; and that this increase of volume sometimes amounts to one-tenth or one-twelfth.

Profiles.

Profiles cannot in moments of need be calculated with mathematical exactness: it would therefore be well if every officer carried with him in his pocket-book a ready-made Table of the dimensions of ditches corresponding to certain given profiles. If unprovided with such a Table, the following approximation will be found quite adequate to the purpose. Ascertain the superficial contents of a vertical section taken perpendicularly to the length of the intended parapet or covering mass. Then assume the depth of the ditch, which will generally be the same as the height of the work. Divide the contents of the profile by that depth, and the result will be the required breadth. For instance, if the ditch is to be six feet deep, and the surface of the profile should contain one hundred and eight square feet; the required breadth will be eighteen feet for the upper part of the ditch. This expeditious formula, indeed, supposes the ditch to be dug vertically down without slope; that there is no augmentation of volume; and that the ditch has no greater developement than the parapet: all which suppositions are contrary to truth. But the ditch being dug with a slope, the surface of its profile will be diminished; and this decrease of surface will partly compensate for the increase of volume and excess of developement, so that the result will be sufficiently correct for actual practice. Or, if the eighteen feet above found be considered as the mean breadth of the ditch, and if there be added to it such an aliquot part of the given depth as is expressed by the proportion of the breadth to the height of the intended slope, the sum will express the true breadth of the ditch at the upper part. Although we have generally spoken of six or seven and a half feet as the height of the parapets, it does not follow that, under some circumstances, still less may not be given to them; but then they lose much of their efficacy, unless the work is situated on an eminence; and if the height is less than four feet and a half the berm must be formed below the level of the natural ground, for the reason given in describing that part of the work. When parapets have more than the ordinary height given to them, it is sometimes impossible to direct their superior slopes upon the edge of the counterscarp. The latter must then be raised by a mass of earth sloping gently towards the country upon the prolongation of the superior slope; or, in other words, by giving a glacis to the work.

See fig. 19

When a work is traced upon the ground, that is, when strong pickets have been driven at all the angles and connected by ropes, or by furrows cut in the ground, two profiles must be set up on each line to designate the form of the parapet, and to point out to the workmen where they must throw the earth. If the face of the work is rather long, two profiles may not suffice; a third must therefore be added in the alignment of the former two. These profiles are made of fir laths when such are to be obtained: in which case they may be set up with all desirable perfection, representing exactly the shape of the parapet. In the first place, there should

be driven two strong square-headed pickets A and B, denoting the thickness of the parapet; against the first of these is nailed a lath AC, equal in length to the required height of the parapet; in like manner there must be nailed against the second picket a lath of indefinite length B; and then at the extremity C of the first, a transverse one, to which is given, by a quadrant, or a mason's level, or even by the eye, the inclination which may be deemed expedient: this done, it may be fastened at the proper point D. The superfluous length of BD must then be sawn off, and the fourth lath DE placed at an angle of 45° with the ground, by nailing it at D, and to the square-headed picket E. The banquette is profiled in the manner indicated in the figure.

Profiles may be economized by constructing them upon the angles; as then, one profile will serve for two faces. These angular or oblique profiles have over the square ones the advantage of designating more clearly the parapets of the works, which facilitates their construction. and obviates unnecessary removals of soil. Some degree of habit is requisite in the construction of these oblique profiles. After having driven into the ground pickets in a direction perpendicular to the magistral line of any face of the work at each extremity of such face, and at distances from one another equal to the horizontal breadths of the several slopes, as in the former profile; ropes or tracing lines are stretched upon the ground in the directions of the capitals at each salient and re-entering angle. Then, by a rope extended in a direction parallel to the magistral line touching any two corresponding pickets, intersections are obtained with the ropes indicating the capitals; and those intersections are marked by other pickets. These will be the places at which are to be raised the vertical poles or laths for determining the form of the profile; and the same heights must be given them as would have been given to the parts of the perpendicular profiles before described. When two angular profiles are set up they will serve for determining those at all the other angles. It may be well nevertheless to establish here and there a square profile to rectify the oblique ones, and to guard against the errors which might creep in. When laths cannot be obtained, branches of trees, however clumsily shaped, may be used to mark the heights, and then with strings or cords the various slopes may be indicated by tying them to the ends of the branches. Besides, when it happens that such means are wanting, it is seldom necessary to model the parapet with great nicety; the essential thing being to get cover, and for this purpose a good relief will suffice, which may be had even without any regular profile. When all the profiles are constructed, the space to be occupied by the parapet becomes known; then there may be traced, at a foot and a half from the foot of the exterior slope, the line representing the edge of the escarp, and at a proper distance, that of the counterscarp.

Tracing of works.

In all the works of which we have given a description, the ditches are usually made of an uniform breadth throughout, provided the parapet has everywhere the same height and thickness; it would, however, be well to diminish the breadth of the ditches at the salient, and widen them at the re-entering angles; because at the former they have more developement than the parapets, and at the latter the contrary is the case. Whence it follows, that, in one instance, the workmen have more earth than they want, and in the other a deficiency, if in aligning the counterscarp, the precaution here suggested has not been taken. Hence, then, the counterscarps of flanked works will not be made parallel with the escarp, but be closer to it at the salients. The exact degree of this approximation at the salients cannot be indicated; and must depend upon correctness of eye and judgment in an officer. In any case it will be better to contract the ditch too much, than to be troubled with a surplus of soil which would exceedingly embarrass the work, and must ultimately be conveyed away to a distance with much labour. It seldom happens that an officer has time to profile a work before the workmen are set about it: the latter are usually placed at his disposal before the work is traced, and he himself conducts them to the ground. Whilst they are resting, he quickly determines his outline by picketing the angles; and as soon as he has approximately fixed the middle of his ditch, he places his workmen there, telling them to what depth they may begin by digging upon a breadth less than the presumed one of the ditch. Whilst the men are doing this, the officer reverts to his tracing; constructs his profiles; makes his little calculation to ascertain the breadth of his ditch; and finally traces with the pickaxe the lines of escarp and counterscarp. Care must be taken to round off the counterscarp at the salients by using the breadth of the ditch as a radius, and the angle of the escarp as a centre.

Distribution of workmen.

The disposing of the working parties in such order that the men shall not embarrass one another, and that the work shall advance in an orderly and expeditious manner, is a most essential object. The work is portioned off into lengths of nine feet, measured along the centre line of the ditch. In each of these divisions is placed a party of five men, one provided with a pickaxe and the other four with spades. Two of the spademen are placed by the side of the pickman, and the other two are placed upon the berm to pitch the earth further in. Besides these five, a sixth spreads the earth upon the mass of the parapet, consolidates it with a rammer, and forms the exterior slopes; this man uses alternately the rammer and spade. Hence there will be six men in each party, being at the rate of four men per fathom, measured along the middle of the ditch. Besides these workmen, sappers, gunners, and other intelligent soldiers should be employed in making the revetments and other delicate details. A corporal may have charge of five parties, and a sergeant may command the fatigue party of the whole redoubt. In sinking the ditch, it has been recommended to excavate as much at first as two or three feet in depth with a breadth less than that of the whole surface of the ground, marked out for it by one or two feet measured from both the escarp and counterscarp, and to cut the sides down vertically; then to excavate an equal depth with a breadth less than the former, by retiring a foot or two from the sides before cut down, and again to cut vertically, and so to continue till the required depth is obtained, by which the sides of the ditch will have the form of steps. These steps are necessary to ascend and descend by; to prevent the workmen from excavating too much; and to assist in fixing the slopes by the height and breadth given to the steps. When the whole mass is excavated, the steps are cut away; first with the pickaxe, and next with a flat spade when neatness is required. The good soil should be carefully preserved for the slopes of the parapets, which must otherwise be formed with earth got from beyond the ditch: every kind of soil not being

equally good for uniting and becoming compact under the blows of the rammer. When works are very hastily constructed, it is impossible to put away the good soil; on the contrary, the covering mass must be formed as fast as possible with whatever comes to hand, and then the stratum of vegetable soil, which is generally the best, is covered over by that of an inferior quality: if the latter is too gravelly, the upper layer must be removed within the terreplein to be used afterwards in forming the exterior of the parapet. In making choice of the site of the work, it will be well to avoid as much as possible rocky and gravelly soils, only covered at top by a slight stratum of good earth. From the commencement of the work means must be provided to carry off the rain-water, which, without this precaution, would stagnate in the terrepleins, and render them uninhabitable. When the work to be constructed is open at the gorge, a drain may be made towards the latter, and the terrepleins on each side may have a gentle slope towards the gutter. But when the work is an enclosed one, a small drain must be made either with flat stones or boards underneath the parapet in that part of the work which is the lowest; taking care to let the spout project sufficiently beyond the escarp to prevent the latter from being furrowed by the stream. It is reckoned that one man may (in easy soil) dig up eight cubic yards per diem of eight hours' work; but this is the case only when the excavation is near the surface, and that one throw will project the earth into the mass of the parapet: when digging rather deeply and in a strong soil, the average quantity of work is six cubic yards per man; and frequently only three or four yards per man, when it is necessary to place a relay upon the berm.

Manner of defilading fortifications.

When a work is not commanded by any eminence within range of musketry or artillery, the plane of site may be considered as horizontal, and as coinciding with the ground on which the work is constructed; and no greater height need be given to the parapets than will suffice to conceal the interior from an enemy standing on the same level plane. But should the enemy be enabled, from any position possessing superior elevation, to direct a plunging fire into the interior of a work having only the relief above supposed, it is evident, that to render such a work habitable, it would be necessary to raise the parapets on the side next to the enemy until they should conceal the terreplein from his view. In determining the heights which should be given to the parapets that they may thus cover the interior, consists the Art of Defilading: which, for permanent fortifications, requires that accurate profiles of the ground within and about the site of the intended works should be taken, by going over it in various directions with the spirit level. These profiles enable the engineer to determine the height of the several inequalities of the ground with relation to an imaginary plane of site passing obliquely to the horizon through the summits of the commanding height on any one side, and coinciding with the terreplein of the work on the opposite side; and thus he has it in his power to compute the elevations which his parapet should have above the ground whereon they are to be raised, in order that they may possess the same command over the oblique plane that they should have had over a horizontal plane if not commanded. But in Field Fortification, where the haste of the service renders such levellings and computations impossible, it is necessary to have recourse to a more simple method of defilading the interior of works; and this we now proceed to describe.

When the work is to be defiladed from a hill in front, or when the line of fire from thence is nearly perpendicular to the direction of the parapet, a tall picket must be set up on the tracing of that parapet at the part which is nearest to the hill. Then, a visual ray directed to a point at the gorge or rear face of the work, eight feet above the ground, from a point four or seven feet above the commanding hill, according as the work is to be defiladed from artillery or musketry, will intersect the picket in a point indicating the height to which the parapet is to be raised on that side of the work. It is evident that this visual ray representing a line of fire from the enemy's position on the hill, a parapet the height of which is thus determined will defilade all the interior of the work. But if from this operation there should result a height greater than can be given to the parapet with the means at hand, the parapet must be raised only as high as such means will permit; and then the interior of the work must be more completely defiladed by a traverse, the situation of which may be thus determined. Find a place on the terreplein of the work where a visual ray from the point before mentioned, on the summit of the hill and passing through the crest of the parapet towards the interior, will meet one at eight feet above the ground; and at the spot thus formed the traverse must be raised: then all the space between the parapet and the traverse will be defiladed by the former, and such a height must be given to the latter as will defilade the part in its rear. This height may be found as that of the parapet was found in the former case. If the height which can be given to the traverse should not suffice to defilade the whole of the terreplein in its rear, the situation of a second traverse must be found by the same process as before. Should there be a parapet on that side of the work which is furthest from the hill, it will be necessary also to put the defenders of that parapet below the plane of defilement, in order to protect them from the reverse fire of the enemy on the hill. For this purpose the visual ray which determines the height of the first parapet or traverse must be directed from the enemy's fire-arm on the hill, not to a point eight feet above the terreplein of the work, but to one eight feet above that of the banquette on which those defenders are placed: the relief of the parapet on this side having been previously determined by the command which it ought to have over the ground before it.

If such a work as a redan or a bastion presents its salient angle to the rising ground from which it is to be defiladed, the height of the parapet at that angle must be determined, as before, by two visual rays, directed to points eight feet above the ground at the lateral extremities of the gorge; and the crests of the parapets of the two faces may lie in a plane of defilement with which those visual rays coincide. Should such a work be commanded by hills opposite to both faces, the reliefs of the parapets must be determined by the coincidence of their crests with two planes of defilement which intersect each other in the interior of the work at eight feet above the terreplein, and pass through the summits of the hills; and at the line of intersection a traverse must be raised, the height of which may be found by visual rays directed to points, each situated at eight feet above the banquette, from the hills in front of the opposite faces. This traverse should pass through the salient angle of the work, that it may defilade the whole

of the interior on each side of it; but its tracing on the ground is not necessarily rectilinear. If the two planes of defilement should not intersect one another above the terreplein of the work, two traverses must be raised where those planes respectively approach within eight feet of the terreplein. Let it be observed, in the last place, that when a work is entirely surrounded by heights it may, with most facility, be defiladed by a pair of traverses crossing each other in the interior.

Formation of the revetments:

Earth will not support itself at the interior slope upon so small a base as it is necessary to give it so that the troops may approach the parapet with ease when firing. It is therefore requisite to revet that slope; and this is usually done with fascines, hurdles, sods, or sand-bags.

with fascines;

Fascines have been already described under the head of siege operations. When employed to form a revetment for the interior of works, the fascines or saucissons are disposed horizontally; the first is half buried in the banquette and is fixed by three pickets driven in with a mallet: these pickets are three feet long. The second row of fascines is placed rather within the top of the first, in conformity with the required slope, taking care to fasten each fascine with three pickets or stakes, the two extreme ones being driven through the fascines underneath in the direction of the slope, and the third in a direction perpendicular to the slope, in order to connect the revetment strongly with the soil. The Austrians substitute for the last-mentioned picket a strong twig with a hook at one end like an anchor, which embraces the whole fascine, and is then fastened at the other end to a stake driven into the mass of the parapet, and covered over with earth: this gives great solidity to the revetment. Fascines are laid in the same manner as bricks or stones in buildings, with the ends of one course over the centres of the other; and at the angles they must be twisted round to avoid any disjuncture. When five courses of fascines or saucissons have been laid down, the upper course nearly reaches the crest of the work; this may then be covered with sods laid flat, with the grass uppermost, to connect them with the earth of the parapet. The exterior slopes of parapets also are sometimes revetted with fascines, when great stability is required; but in this case the fascines should lie in vertical planes against the slope, with the lower ends fixed in the ground at the foot, lest the enemy should use them as steps to ascend the parapet.

with hurdles;

A sort of hurdle revetment also is sometimes formed by planting strong pickets in the direction of the slope, and then weaving or interlacing flexible branches round them. These branches are fastened at the top of the revetment to the heads of the pickets, in order that the hurdling may not detach itself from the parapet.

with sod or turf;

When sods are used for revetting, they are cut in a rectangular shape, two feet long, one foot broad, and six inches thick. They are laid by headers and stretchers, ends over centres, and grass undermost. This last precaution is necessary, in order that they may lie flat, and that they may the more easily be pared with the spade when the revetment is built; and a stake ought to be driven through each sod to fasten it to those which are underneath. To ensure solidity the revetment should be built only in proportion as the work itself advances, care being taken to ram the earth well against the interior sides of the sods. When the revetment is finished, all the rough ends of the sods are shaved off with a spade having its edge formed in an arc of a circle, and sharpened that it may cut off the roots more easily. The sod revetment may be executed with the greatest perfection; and it is always employed in preference to any other where nicety is required. One man may lay sixteen square yards of sod revetment per diem of eight hours' work, when he has the sods ready at hand.

with sand bags,

The interior of a work is also sometimes revetted with what are called sand-bags: these are sacks which, when filled with earth, are about two feet long, one foot broad, and seven inches thick; they are disposed in horizontal courses with their sides and ends following each other alternately in each course like bricks in a wall; and the usual precautions are taken to break joint, or that the junction of every two bags in one course shall be over the middle of a bag in the course below it. This kind of revetment is, however, objectionable, being liable to be washed down by heavy rains; and unless well tarred, the bags burst when very wet.

or with mud.

But it often happens that there are neither woods nor meadows in the neighbourhood from which fascines or turf can be extracted. In such cases the flooring of the nearest houses may be taken up and the materials used for the revetments. If this means be also wanting, a kind of mortar may be made by mixing the most binding earth that can be found with chopped straw, &c.; and this being wetted and well rammed will have such tenacity, as to allow the required inclination to be given to the parapet. In no case must the revetment be made of either masonry or loose stones. The splinters which the shot would produce on such revetments, are more to be apprehended than the shot themselves; because as they fly in every direction, there are no means of finding shelter from them.

Revetment of escarps with trunks of trees or planks.

The slopes of the parapet are not those which alone require a revetment: the earth on the escarp of the ditch, in some cases, requires support; as when, the work being of importance, the soil is not sufficiently stiff to remain at a slope the base of which is one-half or one-third of its height. The escarps of works have sometimes been revetted with trunks of trees placed horizontally; but, disposed in this way, they offer facilities to the escalade, being somewhat like a flight of steps. It would therefore be better to place the trunks contiguously, and on their ends, with a gentle inclination towards the work. But the best mode of all is to revet with strong planks supported by frames, the ends of which are buried in the earth. The figure will sufficiently show the nature of this contrivance without further explanation. See fig. 20. It must nevertheless be remarked to the disadvantage of this carpentry work that, as the tie beams necessarily run into the natural ground, the parapet cannot be modelled before the revetment is finished; it therefore follows that the earth must be heaped up at a distance from the berm, till it can be used in building the parapet. This may be considered as an argument that revetments of the escarp scarcely belong to field fortifications properly so called, but rather to those of a mixed nature.

Of the accessaries to field-works.

When cannon are placed in a field-work, care must be taken to avoid as much as possible making embrasures or port-holes in the parapet for the cannon to fire through, as they weaken the parapet considerably, are marks for the enemy's shot, and facilitate his entrance into the work at the time of the assault: the small opening which it is allowed to give them, moreover, limits exceedingly the space through which the guns should traverse. It would generally be preferable therefore that the artillery should be placed so that it may fire over the parapet.

Fortification.

The mass of earth or platform thrown up for this object is called a *barbette*. Its surface ought to be about two feet and a half beneath the crest of the parapet; but its extent will depend upon the number of guns for which it may be intended. A field piece with its appurtenances requires a space of about eighteen feet by fifteen. Hence the platform or terreplein of the barbette destined to contain one gun, will be a rectangle having its length, in a direction parallel to the parapet, equal to fifteen feet; and, in a direction perpendicular to it, eighteen feet. The ascent to the terrepleins of barbettes is made by ramps or inclined planes, the base of which should be equal to six times their height; and their breadth is obviously regulated by the length of axletree of the gun-carriages which are to pass over them. It is not unusual to provide against the danger of a side or enfilade fire, by erecting on each side of the guns a traverse six feet high at least: and in order that these shall occupy the least possible space, it is usual to make them of gabions filled with earth, placed in two or three rows on the terreplein, and having two courses in height. Gabions have already been described in the attack of fortresses: when used for traverses, and generally for intrenchments, they should be three feet high and two feet in diameter.

Entrances into field-works.

The entrance into a field-work is cut through the parapet, and the sides are kept as steep as possible to diminish the exposure of the interior of the work. The entrance is not made wider than is absolutely necessary to afford a passage for the cannon; and it is closed by a barrier or *cheval-de-frise*. A cheval-de-frise is a beam or prism of timber, the section of which is either a square or hexagon, with spears passed through it.* It may here be remarked, by the way, that for the defence of works, chevaux-de-frise are also placed on the berms, in the ditches, or on the exterior. They are placed in line, and are linked together by means contrived for the purpose at each of their ends. The prism is usually about twelve feet long. The spears or staves are about six feet long and two inches in diameter, and are made either round or square. This is rather a complicated machine, and one which would require proper materials for its construction, and artificers accustomed to that kind of work. The facility also with which chevaux-de-frise are destroyed by a few rounds of artillery, has caused them to be disused of late: so that they are no longer carried about with armies, and are scarcely ever employed but as barriers at the entrances of a field-work. The required communication between the counterscarp and such entrances is made by throwing four or five beams across the ditch, and placing boards or planks transversely over them. In a moment of danger these are pulled away, and converted if necessary into means of strengthening the entrance barrier. When the ditch is more than twelve feet wide, a trestle may be placed in the middle to support the beams. It may sometimes happen that the bridge is upwards of twenty or twenty-four feet long; in these cases more trestles must be employed, and care must be taken not to place them at a greater distance from each other than twelve feet. It is absolutely necessary that the powder of a field-work should in some way or other be sheltered both from damage by rain and by the fall of shells. When therefore time and means are allowed, a splinter-proof magazine may be constructed in an appropriate part of the work: for instance, under the mass of a large traverse. But should these be wanting, a good practice, and one which has often been tried with success, is to bury the powder in the mass of the parapet, having placed it in any common box which may have served for the transport of ammunition, the cover side serving as a door, to which a lock may be put if one is at hand; but whether or not, a sentry is placed near it to prevent accidents.

Bridges over the ditches.

Powder magazines.

CHAPTER VI.

On the Means of adding to the Strength of Field-works.

The ditches of field-works being usually of an inconsiderable depth, can hardly be regarded as efficient means of stopping an enemy: for if they are but six feet deep, (and the haste with which such works are usually thrown up will rarely permit them to be deeper,) he will easily jump into them, loaded as he may be with arms and knapsack. The dead angles also of those ditches, where the enemy will be perfectly secure, will give him time to breathe, rally, and form for the assault. It is therefore necessary to place obstacles upon the approaches to those points. Now as the salients are in all works the weakest points, all the resources of art must be employed to retard or arrest the enemy's march towards them, to throw him into disorder, and keep him a long time under the fire of the work. The best of all obstacles is an *abattis*: which is a barrier formed of strong interlaced branches of trees stripped of their leaves and smaller parts, sharpened at their extremities, and presenting outwards a cluster of points. They are fastened to the ground at the thick end, and screened from the enemy's sight by an advanced glacis, the slope of which is upon the prolongation of the crest of the parapet; the earth requisite for the purpose is taken from behind it upon the production of the slope of the original glacis. Trees or branches thus placed can with difficulty be removed by hand; and cannon shot produces but little effect in deranging them: the only effectual method therefore of destroying them would be to set them on fire. *Trous-de-loup* are excavations in the form of inverted cones or inverted pyramids, six feet deep and six feet wide at top; they are placed in chequer and six feet asunder, and are sometimes covered with furze or light branches, to conceal them from the sight of the enemy. Trous-de-loup are excellent means of arresting the march and breaking the ranks of the assailants. The earth resulting from the excavation being piled up on the sides, renders the ground exceedingly uneven, and prevents the formation of any kind of order in the attack: but, as it is attended with the evil of raising the ground two or three feet, trous de loup are only admissible where the parapets of the works have a command of seven or eight feet over the country: otherwise, it is necessary so to strew the earth about as to form no sensible elevation. At the bottoms of these holes strong stakes are driven in with sharp points upwards; their use is to prevent the enemy from taking cover in them against the fire of the works. It is thought however that active riflemen would make use of them as covers, from within which they might pick off all who should show their heads above the parapet. Trous-de-loup may be employed in several cases: as first, in front of lines, to render their access more difficult and retard the march of the attacking columns. Secondly, against cavalry when any particular part of a front requires to be screened from its attack. And lastly, Guy de Vernon

Abattis. See fig. 21

Trous-de-loup.

recommends them strongly to be employed in the bottoms of the ditches of field-works.

Crows' feet. Crows' feet are pieces of iron with four points diverging from a centre, and so made that whichever way the mass falls, one point will always be presented upwards. They were formerly very much used, being strewed over roads where the passage of the enemy's cavalry happened to be unavoidable. Some recommend strewing them in quantities over the glacis or on any of the approaches to field-works: but for this purpose they are not so good an expedient as small pickets or stakes planted in great numbers, and projecting six or eight inches above ground. The harrows used by labourers would be of great service, if buried so as to leave only their points above ground.

Pickets and harrows.

Inundations. Whenever local circumstances permit the ditches to be filled with water to the depth of five or six feet, this means of defence should not be neglected; as not only the defect of dead angles will be completely remedied, but the enemy will be forced to employ more than ordinary means to approach the work. If a small river or rivulet passes within musket range of the work, the difficulty of access to the latter may be increased by throwing up some dikes across the course of the river, thereby spreading an inundation over the adjacent ground. These dikes are so placed as to be enfiladed or flanked by the fire of the work; and when time and workmen are not wanting, the most exposed amongst them may be covered or supported by a small redan to prevent the enemy from arriving at them and draining off the waters of the inundation. Experience has proved that a good dike should not be higher than nine feet: hence, from one dike to another, when several are used, the difference of level between them should be only four feet and a half, in order that the most shallow parts between two dikes shall not be fordable. Therefore, after fixing the place for the first dike, that of the others will depend upon the natural slope of the waters, which must be determined by levelling, or ascertained by information obtained from the neighbouring millers. The level of the second dike will be placed four feet and a half lower than that of the first; the third as much lower than the second, and so on with the rest. Hence it follows that this kind of defence is inapplicable to a mountainous country, because the slopes are too great: it is equally so to a country where the bed of the river is not sufficiently confined, and has its borders too far apart; because the dikes, in this case, would require too considerable a length, which would entail extraordinary labour in the construction, and difficulty in the defence.

It is impossible to fix a limit for the length of a dike, because its construction depends upon the means at disposal. In some cases a dike one hundred yards long would appear a prodigious undertaking: in other circumstances the construction of such a dike would be sufficiently practicable. But as neither the profile of a dike nor the length of its fall for the evacuation or running off of the superfluous water are dependent upon its length, some details upon the subject may be given. When a dike is not liable to be battered by artillery, a thickness at top of four feet and a half will suffice, supposing the dike to be made, as it most generally is, of earth. The earth may be taken from the lower or ebb side; and if it be not sufficiently binding and lets the water filter through it, proper earth must be brought from the neighbouring country wherever it may be found. This will augment the trouble, but is indispensable for the goodness of the work. The best way to prevent filtration is to line the inside of the dike with clay. When the dike is exposed to cannon its summit ought to be proof, that is, about nine or ten feet thick. Its natural slope may be given to the earth on both sides the dike; but for greater perfection, the upper slope, that is, the one on the flood side, should be made the gentlest, by giving its base twice the length of the dike's height; to avoid the shock of the stream and diminish its pressure.

If after constructing the dike with earth according to the profile above indicated, the waters were allowed to rise above it and flow over the whole of its length, it would not be long before the whole dike must be destroyed, supposing the current were at all rapid. To avoid this inconvenience, a space is left eight or ten inches lower than the rest of the dike, and of sufficient breadth to allow a free passage to all the water of the stream. This part forming a cavity on the top of the dike, and constructed more solidly than the rest, is called the fall or deversoir. This fall is constructed with fascines, that is, after building the dike to a certain height, a double revetment of well picketed fascines is commenced: this revetment must not only cover the top of the fall and the ebb side slope, but must extend underneath, forming a bed to break the fall of the water and prevent its undermining the foot of the dike. With respect to length, this bed is made to extend a little beyond each extremity of the fall, in order that it may more completely fulfil its object. To give greater solidity to the bed of fascines, the tops of the pickets which are driven through the mass, may purposely be left a little above ground, and have hurdle-work interwoven round them. The pickets or stakes ought to be four feet and a half long. The same hurdling might be made on the revetment of the fall; but if this should appear too laborious, the extremities of the fascines should at all events be secured by others placed crosswise and strongly picketed into the first. The cheeks of the fall are likewise revetted with fascines, which are placed at right angles with those of the top of the fall and picketed into them. See fig. 22.

When any part of the ground about the accesses to the work is low and marshy, but destitute of such currents of running water as would permit an inundation to be formed, holes or trenches five or six feet deep and as many wide may be substituted. These holes and trenches will effectually stop the enemy; and he will be obliged to fill them up before he can arrive at the counterscarp which they cover. The above-mentioned breadth will be quite sufficient to render them impassable for men loaded with arms, ammunition, and knapsacks. The earth excavated must be carefully and evenly strewed about, both to prevent its forming small islands which would assist the assailants, and because any rise of ground, in the vicinity of a field-work may be detrimental, owing to the small relief usually given to the latter. If the localities be such as offer to the enemy the facility of draining the inundation or sheet of water, the holes and trenches above mentioned may be multiplied, as they will contain water and be a serious obstacle even after the draining is effected.

Palisades. Palisades for field-works are made of strong branches or rather trunks of small or middle-sized trees, split into two or four parts, and generally cut into triangular prisms having each side six or seven inches broad; but whether they are used in their natural round state or

Fortification.

sawn into prisms or split in two, their efficacy is the same. Their length is nine feet, and they are sharpened at the upper extremity. The best place for palisades is at the foot of the counterscarp: because they are there most screened from the enemy's shot, and embarrass him most in his attempt to get into the ditch. If the palisades were placed contiguously, forming a *palanque* for the defence of the ditch, it would then be necessary to put them at the foot of the escarp; but when merely employed as an obstacle, which is most generally the case, they should be placed as above mentioned at the foot of the counterscarp. To plant palisades, a trench is dug three feet deep, and as narrow as possible; and in it they are placed three or four inches asunder. The earth is then well rammed down round them so that they shall be firm; and they are united at top by a riband or cross beam, against which each palisade is nailed. It would be still better if they were likewise fastened at bottom to a cross beam buried in the ground, for this would utterly prevent them from being torn up separately.

fig. 21. *Fraises* are nothing more than palisades placed horizontally or slightly inclined to the horizon, with their points downwards: they are usually placed upon the summit of the escarp, and then, notwithstanding the precaution of throwing up a glacis to cover them, they are soon destroyed by the enemy's cannon. Nevertheless great advantage is gained when he can be forced to do this: for during the whole time he is so employed, his fire, which is ricochet, is returned with interest by the artillery of the work with full service charge. The inclination given to fraises is intended to prevent the grenades, which are thrown into the ditch, from lodging upon them. Fraises must be placed as nearly contiguous as possible that the enemy may have the more difficulty in cutting them down with the hatchet, or in sawing them off. The placing of both palisades and fraises is a subject which merits to be well weighed: there being instances in which instead of opposing, they have contributed to facilitate the assault.* The length of the fraises ought to be at least ten feet and a half, in order that they may project four feet and a half beyond the escarp: about one foot and a half rests on the berm; and the remaining four and a half feet are buried in the mass of the parapet. They are nailed to a cross beam sunk into the berm; and that they may be firmly connected, another cross beam buried in the parapet unites their superior extremities.

Fougasses are perhaps the best of all means of stopping the impetuosity of an assailant: but unfortunately they cannot in every case be employed. When the besieger is aware that the work is provided with fougasses, and this he should be suffered to know, his timidity and circumspection will be extreme. Soldiers who have once witnessed the springing of one of these small mines, are in continual apprehension of explosions; and a hidden danger which they cannot anticipate produces upon them a much stronger apprehension than they are susceptible of feeling at perils of a more serious nature, when openly encountered. The effects, indeed, which mines produce upon the *morale* of assailants are perhaps the greatest advantage which they afford to the defenders. To establish a fougass, there should be buried, at the depth of a few feet, a box containing three or four loaded howitzer shells, or else about twenty pounds of powder. This box is communicated with by a wooden trough, which is likewise buried in the ground, and is destined to convey the fire to the charge. In order to place it, a narrow trench is dug, of the required depth; and after charging the mine and laying the powder pipe in the trough, the lid is carefully fastened down. The trench is then filled up again with earth, taking care to ram it down well, and scattering about the surplus on the surface. The well or hole which has been excavated to contain the charge, is, after the latter has been placed, filled up with stones instead of earth, to render the effects of the fougass the more destructive. The trough passes down the counterscarp under the bottom of the ditch, through the thickness of the parapet, into the interior of the work. It is sometimes made to stretch across the ditch, and is then supported by trestles; but this arrangement exposes it to continual accidents. If the box containing the charge be likely to remain long under ground, it is necessary to calk and tar it, as well as the trough, to preserve their contents from damp. Great care must be taken to guard against precipitation when about to spring a fougass, otherwise the chances are that it will explode before the enemy reaches the sphere of its effects. Fougasses are very advantageous at the angles of dead ditches, where they may be placed about ten feet asunder; and also at about ten or fifteen paces from the ditch, at those points over which the enemy is most likely to advance. The chief and perhaps only objection to them is that they seldom act at the precise moment when the enemy is immediately over them; unless therefore there be placed an abattis or some such obstacle to retard him there until the explosion takes place, his destruction by this means will be very doubtful. See fig. 21.

Defence of dead ditches.

When an enemy succeeds in getting into the ditch of a field-work destitute of flanking defences, he is perfectly safe from every thing but hand grenades; and it is not always that a supply of these can be commanded. It is therefore of importance that means should be employed to obviate so great an evil. If the work is a lunette, there may be placed a *palanque*, that is, a row of strong palisades across the ditch at the angles of the shoulder. Loop-holes are of course made at proper distances for the purpose of permitting a cross fire of musketry upon the salient. For a square redoubt, the simple palanques above mentioned are inadmissible because they defend only one side. Double palanques are therefore used, which are placed at two opposite salient angles, so as to sweep the whole of the ditch and have a cross fire upon the other two remaining angles. The palanques are covered at top with thick planking and fascines: and to screen them from fire, a bed of earth or manure may be laid over the top. A double palanque, or covered gallery of this kind, receives the name of *caponnière*. The descent into this caponnière is effected from the interior of the redoubt, by a passage cut underneath the parapet. The outer extremity of the caponnière is not made to reach the counterscarp; for, if so, it would soon afford the enemy a safe means of crossing the ditch. A portion of the counterscarp is therefore cut away at the head of the caponnière to isolate the latter. The small width in general given to the ditches, and the great quantity of timber necessary for the construction of the caponnières, are the reasons of their being seldom employed: they are, in fact, a means of defence which cannot be resorted to, otherwise than in cases where there is plenty of time at command, and timber in the neighbourhood.

Palanques. Caponnières.

* See Major Reid's translation of Col. La Marre's Defence of Badajos.

Fortification.

Counterscarp galleries of reverse fire.

Another expedient sometimes adopted, is that of loop-holed galleries underneath the mass of the counterscarp, for the purpose of having a reverse fire along the ditch. A communication is made from the interior of the work into these galleries of reverse fires, by a gallery driven underneath the bottom of the ditch. If the objection to the caponnières, arising from the great consumption of time and timber which their construction demands, be a just one, it applies much more strongly to these works which, for the same reasons, can be very rarely executed.

Interior redoubts.

The surest way to support the courage of the defenders, and consequently to increase the strength of a work, is to facilitate their means of retreat in case they should be overcome; and thus to procure for them a place of refuge, in which they may capitulate upon terms the more honourable in proportion as they have defended with gallantry the principal work. This may be accomplished by the construction of an interior redoubt, when the magnitude of the principal work will permit it. In forming such redoubts, care should be taken to dispose them in such manner that there shall not be a single point within the principal work undiscoverable by their fire; and their size must be adapted to the numbers for which they may be required to afford cover. If the principal work be one of a considerable extent, the redoubt may be made with earth, like an ordinary retrenchment, that is, with a parapet and ditch. But then a command must be given to it over the parapet of the exterior work, in order that the enemy when standing upon the parapet of the latter may be unable to see into the redoubt. The best kind of interior redoubt is that called a blockhouse, which we are next to describe.

Blockhouses.

Blockhouses are a species of retrenchment peculiarly adapted to woody countries: because the materials for their construction are found upon the spot; and as these countries are mostly mountainous, the enemy cannot without much difficulty transport his cannon with him. There is besides in such countries difficulty in finding a site whereon to construct a work of the ordinary uncovered kind, which may not be seen into and commanded by some neighbouring height. The plan of a blockhouse is usually that of a rectangle eighteen or twenty-four feet wide in the inside: but when it is possible to give it greater dimensions, its plan is that of a cross so that its fires flank one another mutually. The profile of a blockhouse will vary according as it may be liable to an attack of infantry merely, or of infantry with artillery.

Blockhouses opposed to infantry only.

In the former case its sides may consist simply of rows of contiguous trunks with loop-holes made in them three feet asunder. In order that the enemy may not be able to set fire to the blockhouse, he must be kept off from it by a ditch, the earth of which is piled up against the blockhouse as high as the loop-holes, and is moreover employed to cover the roof and form also a small glacis round the work.

Blockhouses intended to resist cannon.

The only difference between a blockhouse intended to resist artillery and that which has been just described is, that, instead of a single row of contiguous trunks of trees or piles, the former is constructed of a double row; the interval between them being filled with well-rammed earth as high up as the loop-holes, the whole composing a wall three feet thick. This work being of a more important nature than the preceding one, its inside dimension should be twenty-four feet, and the tie beams, owing to their length, must be composed of two pieces scarfed in the middle, and moreover supported by strong stanchions reposing on a groundsill.

American field-works.

But this description of the mode of erecting blockhouses, being confined to the usual practice of European service, would be incomplete without some reference to the peculiar construction and employment of similar defences in the forest warfare of North America. By the universal expertness of the backwoodsmen of that country in the use of the axe, works of the kind are constructed with astonishing rapidity, and rendered capable of opposing a formidable resistance. The Americans build their blockhouses, like ordinary log-habitations in their new settlements, of thick, horizontal trunks of trees, roughly squared; and several of these works, disposed like bastions at the angles of an area, in such order as to flank each other, and connected by a stockade, or curtain of close palisading of upright trunks of trees, loop-holed for musketry, compose a temporary field-fort of no despicable strength. Even when artillery can be brought against these works, their defenders, protected by interior traverses of earth, suffer little loss: while the blockhouses and stockades, being formed of green timber, do not easily admit of being breached; and may equally—as was proved in one instance, during the last war on the Canadian frontier,—defy any attempt to set them on fire with red-hot shot. Against mere musketry or an open assault, it is evident that, if well defended, the nature of such enclosed and flanked buildings can leave a garrison little to fear. The American blockhouses have sometimes an upper story, projecting sufficiently over the lower, to afford a plunging-fire, through the loop-holed floor, upon the assailants at the foot of the walls.

CHAPTER VII.

Attack of Field-works.

Having detailed the outline and relief of the various works thrown up in the field, and having pointed out the means by which such works may be rendered most difficult of capture, this Essay may appropriately terminate with a brief account of the manner in which intrenchments are attacked. If they are of little strength and importance, and unprovided with artillery, the assault is given without any previous cannonading. The light troops surround the post, directing upon the crest of the parapet a shower of bullets, to prevent the defenders from showing themselves, or at least to force them to fire precipitately and without aim. If nothing protects the access to the counterscarp of the work, the assailants jump into the ditch and prepare for the assault; a part of them remaining upon the counterscarp to keep down the heads of the defenders. When the troops have had time to breathe in the ditch, they give the assault, the men helping one another to climb up to the berm; whence, with a fresh effort they rush all together up the exterior slope, fire a volley, and then move at once upon the defenders to compel them to surrender. If, instead of the feeble intrenchment which we have just supposed, the work to be attacked were a large field fort, provided with an interior redoubt, armed with cannon, and strengthened with abattis, trous de loup, fraises, and palisades, destined, in short, for a long defence, the dispositions for attacking it would be very different. It must, in the first place, be reconnoitred, in order to ascertain, as nearly as possible, the nature of the obstacles to be overcome, the number

of cannon, and how they are placed, and likewise every detail of the ground about the work: in order that the measures taken for the assault may be properly executed even at night. Batteries are then constructed; and when ready, the howitzers commence ricochetting with shells, ploughing up the slopes of the parapets, and demolishing the fraises, disarranging and cutting up the abattis, dismounting the artillery, and destroying the troops: while the cannon fire with full charge and directly through the embrasures, converting the merlons into a heap of rubbish and dismounting the guns. When the cannon of the work is silenced, the light troops, who until then only occupied the intervals between the batteries, (not to obstruct their fire,) now surround the work, enveloping it in cross fires. The infantry, drawn up in as many columns as there are salients to the work, move forward, and the signal of assault is given. The abattis may arrest the progress of the troops until a passage be cut through it by the hatchets of the pioneers who march in front; and whilst this is being effected the battalions with supported arms remain exposed to all the fire from the work, without being able to answer it. The light troops however should, in the mean time, redouble their efforts to keep down the enemy's fire. The obstacle being overcome, the columns again move on in close order; the foremost men throw planks over the trous-de-loup, and prepare the way for the rest; when arrived at the counterscarp, the assailants descend into the ditch; cut away the palisades if there be any; rally; draw breath; and then rush to the assault, entering through the embrasures or passing over the parapet. In short, after a struggle, more or less protracted, the colours of the assailants are planted on the most elevated part of the intrenchment; the defenders, borne down by numbers, have ceased to resist; and withdrawing into the redoubt, there demand a capitulation, which a generous victor cannot refuse.

EXPLANATION

THE CHIEF TECHNICAL TERMS USED IN MODERN FORTIFICATION.

Abattis. A line of felled trees with their branches pointed towards the enemy, to obstruct his advance.
Advanced-work. Any defensive construction placed in front of the *covert-way*, but within range of the artillery of a fortress.
Approaches. See *Zig-zags*.

Banquette. A step to enable infantry to fire over a parapet.
Barbette. Any raised platform to enable cannon to fire over the parapet.
Bastion. A principal work in the enceinte of a place, composed of two faces projecting outwards, and two flanks.
Batardeau. A dam across the ditch of a fortress, to retain or let off the water at pleasure.
Battery. Any area on which cannon, mortars, &c. are placed to fire against the enemy's works.
Berm. A narrow path left between the parapet and edge of the ditch before it.
Blindage. See *Splinter-proof*.
Blockhouse. A covered building, generally of wood, for defence.
Body of the place. All works within the main ditch.
Bomb-proof. See *Casemates*.
Breaking ground. Commencing the trenches in a siege.

Camouflet, or *Stifler.* A small mine formed in the earth between two parallel galleries, to cut off the retreat of the enemy's miner.
Capital. A line imagined to bisect the projecting angle of any work.
Caponnière. A screened communication between two works.
Casemate. A vault of brick or stone, to cover artillery or to lodge troops, generally formed in the mass of the rampart, and always made bomb-proof: that is, of sufficient thickness and strength in the roof and sides to resist the effect of shells, projected from mortars.
Cavalier. Any elevated work in the *enceinte* of a fortress or in the trenches of attack, to give a command over the enemy.
Chamber of a mine. The excavation which contains the charge of gunpowder.
Chevaux de frise. Obstacles composed of horizontal beams, bristled with pointed stakes, sword-blades, &c.
Circumvallation. A line of works drawn round a fortress to exclude succour.
Coffer. A sunken *caponnière*, or trench for defence, generally covered, and lined with brick-work.
Command. The height of one work above another, or above the natural ground.
Cordon. The horizontal moulding which usually crowns the *revetment*, which see.
Counter-approaches. Trenches executed during a siege by the defenders, to outflank those of the enemy.
Counter-arches. Circular walls connecting the tails of *counterforts*, or arches built, in tiers, behind a *revetment* and between the counterforts, to resist the outward pressure of the rampart. See *Revetment*, and
Counterfort. An interior massive buttress of brick or stone, to strengthen the *revetment*, which see.
Counterguard. An outwork, covering the face of a bastion or ravelin.
Countermine. A mine used in defence.
Counterscarp. The exterior side of a ditch.
Countervallation. A line of works to prevent egress from a fortress.
Coupures. Traverses with a ditch in front, formed across the *terre-pleins* or upper surfaces of ramparts.
Covert-way. A communication round the works of a place in front of the ditch, and screened by a *glacis*, which see.
Crater. The excavation produced in the earth by the explosion of a mine.
Cremaillère line, or *Indented line.* A continuous parapet, forming a series of alternate branches and crotchets respectively parallel to each other. The interior slope of a parapet, when cut so as to form short faces alternately parallel and perpendicular to the capital of the work, is said to be *en cremaillère*.
Crest. The highest ridge of a parapet.
Crown-work. A double hornwork. See *Hornwork*.
Cunette. An open drain running along the middle of a larger ditch.
Curtain. The connecting line of rampart or parapet between two projecting works.

Dead-angle. That which is without flanking defence.

Deblai. The earth thrown out in the act of excavating the ditch.
Defilade. To screen the interior of a work, by a proper height of parapet, from the fire of the enemy.
Ditch. The excavation in front of a work, from which the earth to form the rampart or parapet is usually obtained.
Demilune, or *Half-moon*. See *Ravelin*.
Detached work. Any defensive construction placed beyond artillery range from a fortress.

Embrasure. An opening cut in the parapet for cannon to fire through.
Enceinte. The main rampart immediately encircling or surrounding the area fortified.
Enfilade. To sweep the interior of a work by a line of fire parallel to its front.
Entrenchment. Any defensive cover obtained by excavation.
Epaulement. In strictness, that elevation of earth which forms the wings of a battery, and covers the guns in flank: but the term is often, though improperly, used to signify the parapet in general of a battery.
Escarp. The interior side of a ditch.

Face. A line of rampart, usually forming one side of a projecting angle.
Fascine. A large faggot.
Fausse-braye. A low rampart in front of, and formerly attached to, the *enceinte*, which see.
Flank. The line of rampart or parapet between the face and gorge of any work, which defends either the collateral ground, or the fronts of works thereon constructed.
Flèche. A simple redan usually constructed at the foot of a glacis. See *Redan*.
Fougass. A small mine.
Fraises. See *Palisades*.

Gabion. A cylindrical basket open at both ends, planted on the ground to sustain the earth forming a parapet.
Gabionade. A parapet formed of full gabions.
Gallery. Any subterranean passage in mining.
Glacis. A parapet with a gentle slope terminating on the level of the exterior ground.
Gorge. The interval between the rear extremities of a work.

Hand-grenade. A small shell thrown by hand.
Hornwork. An advanced work composed of two half bastions and a connecting curtain.

Intrenchment. See *Entrenchment*.
Investment. The operation of confining a garrison within its defences.

Lines. A general term for any long extent of defensive works.
Lines of defence, are those supposed to be drawn from the projecting angle of a work to the interior extremity of the flank which is to defend it.
Loop-holes. Small apertures cut in walls or timber work for musketry.
Lunette. An advanced work in the shape of a bastion.
Magistral line. That which is first traced on the ground, or on paper, to express the contour of the plan of any work. In Permanent Fortification it is supposed to correspond to the cordon of the revetment.
Main-ditch. The principal ditch in a fortress immediately in front of the *enceinte*, which see.
Merlon. The portion of a parapet between two embrasures.
Mine. A subterraneous gallery and recess, to contain gunpowder for destroying, by its explosion, the enemy or his works.

Orillon. A projection at the shoulder of a bastion, covering the flank from exterior observation.
Outwork. Any defensive construction between the *enceinte*, or main rampart, and the ground immediately beyond the ditch.

Palanque, or *Palanka*. See *Stockade*.
Palisades. Rows of strong pointed timbers planted upright in the earth at small intervals. When not upright, and planted in the slopes of parapets, these are termed *fraises*.
Parados. A screen for defence against a fire in reverse, or behind.
Parallel, in a siege, is a trench nearly equidistant in all its length from the works of the fortress attacked.
Parapet, or *Breastwork*. The mass of earth which covers the fenders from the fire of the assailants in front.
Pierriers. Small mortars for projecting showers of stones, &c.
Place of arms. Any area destined for assembling bodies of troops; sometimes the parallels in a siege are so called.
Plane of defilement, is supposed to coincide with the crest of a work and the enemy's fire arm on the exterior ground.
Plane of site. The surface of the ground on which a work is constructed, if not commanded; when commanded, the plane is oblique to the horizon, and passes through the summit of the height.
Postern. A covered passage through the rampart into the ditch.

Ramp. An inclined plane for ascent or descent to a work.
Rampart. The mass of earth which encloses and screens the interior of a work, and on which its artillery and troops are placed in the defence.
Ravelin. A principal outwork, projecting in front of the curtain between two bastions.
Redan. A work consisting of two faces forming a projecting angle, employed to cover troops, or the entrance to a principal work; when two or more are connected by curtains they form lines of intrenchment.
Redoubt. Any enclosed work undefended by re-entering or flanking angles. Also, any work constructed within another, to serve as a place of retreat for the defenders of the latter.
Remblai. The mass of earth accumulated from the excavation of the ditch.
Rentrant or *Re-entering angle*. Any angle of a work of which the vertex points inwardly.
Retrenchment. Any work constructed in the interior of another to prolong its defence.
Revetment. Any wall sustaining the side of a ditch.
Ricochet. A mode of firing artillery, by which the shot is made to bound along a plane surface.

Salient angle. The projecting angle formed by the faces of any work. The ground in front of such angle is in common parlance called the salient of the work.
Sally-port. A gate beyond the ditch.
Sap. The process of executing approaches in siege operations behind gabions.
Saucisson. A long *fascine*, which word see. Also the tube or hose containing the gunpowder by which a mine is fired.
Shaft. The vertical descent into a mine.
Shoulder. The angle formed by the face and flank of a work.
Splinter-proofs. Blinds or covered buildings of carpentry or brick-work, of sufficient strength for protection against fragments of shells, grenades, &c.
Star-forts. Works enclosing areas and having faces disposed so as to form a series of angles alternately projecting and retiring.
Stockade, or *Palanka*. A row of trunks of trees or stout timbers, planted upright, close together, and usually loop-holed for musketry.

Tambour. A small enclosure of timber or brick-work, pierced with loop-holes for musketry. Small areas enclosed by parapets of earth are also so called.
Tamp. To close up the entrance to the chamber of a mine, so that the explosion may not find vent through the gallery.
Tenaille. A low work in the main ditch of a fortress.
Terreplein. The interior area of a work; also the upper surface of a rampart.
Tête-de-pont. Any work constructed on the bank of a river with its rear bounded by the stream in order to defend the approaches to a bridge.
Tower-bastion. A tower of stone or brick in the form and situation of a small bastion.
Traverse. Any mass of earth across the interior of a work for protection against enfilade or ricochet fire.
Trenches. The excavations made in a siege for cover against the fire of the fortress.
Trous-de-loup. Holes or pitfalls with stakes planted at the bottom, to obstruct the advance of an assailant.

Zig-zags, or *Approaches*. The trenches by which the besiegers advance, in oblique directions, towards the works of the fortress.

Naval Architecture.

Introductory remarks.

(1.) It is impossible to contemplate the Naval power of England, and not to feel a deep interest in its history and growth. Such an inquiry cannot but command our attention, mingled up as it is with the elements of our political power, and forming the foundation of all that influence which the name of Britain has for so long a period maintained in the World. The limits of an Essay, like that upon which we are about to enter, will not, however, permit us to do more than glance at a subject connected with so many splendid names, and so many transcendent events,—with victory and conquest in their largest sense,—with civilization and the whole train of the useful Arts,—with all that can impart an interest to a Nation like our own, and to the wide and extended empire of Man.

Division of our Naval history.

(2.) It has been usual to divide our Naval History into three periods: the first embracing all that preceded the reign of Henry VIII.; the second ending with the Restoration of Charles II.; and the last descending from the time of the Restoration to the present day.

Henry VII.

(3.) The first ship actually belonging to the Royal Navy was the Great Harry, built by Henry VII. in the third year of his reign, at an expense of £14,000; this Monarch being the first who thought of raising a Naval force sufficient for the service of the State. Prior to this our Kings had neither arsenals nor dock-yards; and by the Report of the Commissioners for Revising and Digesting the Civil Affairs of the Navy, (1805,) it appears, that the permanent Naval force of our Monarchs consisted only of fifty-seven vessels, each carrying twenty-one men and a boy, as well armed and fitted for war as the circumstances of the times would permit. The Cinque Ports were bound by their Charters to furnish these vessels annually, free of expense, for fifteen days, after receiving forty days' notice from the Crown. Whenever a greater force was required, ships were hired from the merchants at home, or from those of Dantzic, Hamburg, Lubec, Genoa, and other ports.

No Dock-yards.

Henry VIII. Admiralty and Navy Board formed.

(4.) The Naval power of England began to assume a regular and systematic form during the reign of Henry VIII. That Monarch formed an Admiralty and Navy Board, founded the Trinity House, and established the Dock-yards at Deptford, Woolwich,* and Portsmouth.† He drew up a code of regulations for the Civil government of the Navy, which has formed the basis of all the instructions from time to time issued respecting it. Henry appointed several great officers for carrying into execution his Naval plans; *viz.* a Vice-Admiral of England, a Master of the Ordnance, a Surveyor of the Marine Causes, a Treasurer, Comptroller and General Surveyor of the Victualling department, a Clerk of the Ships and Clerk of the Stores. These officers were commanded to meet once a week at an Office on Tower Hill, to consult together for the good order of the Navy, and to report their proceedings monthly to the Lord High Admiral. Notwithstanding, however, this approach to a regularly organized system in Naval affairs, the ships belonging to the Crown formed only a part of the Naval force employed in time of war. The tonnage at this time, according to Mr. Derrick's *Memoirs of the Navy*, amounted to 12,455 tons, and the mariners and soldiers to 7730.

Edward VI. Encouragement given by him.

(5.) During the reign of Edward VI. encouragement was given to the increase of seamen by preventing the trade from being carried on in foreign bottoms. The fleet at this time was divided into a Summer Guard and Winter Guard, the former consisting of 2540 tons and 1730 men, and the latter of 2150 tons and 1516 men. The tonnage at the death of this Monarch amounted to 11,065 tons.

Mary. Diminution of Navy.

(6.) During the reign of Mary, the fleet diminished exceedingly. At her death the tonnage amounted only to 7110 tons, and the ships and vessels to twenty-six.

Elizabeth. Encourages the Navy.

(7.) Elizabeth attended to the Navy with peculiar care. She ordered a rigid inquiry to be made into its condition and the causes of its late decay. She commanded timber to be preserved for ship-building, caused her magazines to be filled with stores, and ordered many pieces of brass and iron cannon to be cast. She encouraged her merchants to build larger vessels for the purpose of being converted into ships of war, when necessary; and what is singular, her Commissioners had the power of rating them 50 or 100 tons more than their actual admeasurement. To stimulate her own ship-builders, she went to Woolwich to the launching of a new ship, and called her by her own name. She augmented also the pay of her Naval officers, raised the wages of her seamen, and invited to her dominions foreigners who were skilled in the Art of Navigation. She encouraged, also, the younger branches of her Nobility to enter the Navy, and settled a part of her revenue, amounting to £9000 a year, towards its ordinary supply. Sir Francis Drake and Sir John Hawkins, two renowned Commanders, advised the establishment of a Chest at Chatham for the relief of seamen wounded in their Country's service. The proud titles of Restorer of the Naval power and Sovereign of the Northern Seas, were hence justly bestowed upon Elizabeth. At the time of her death, the Royal Navy consisted of forty-two ships of 17,055 tons burthen, and manned by 8346 seamen. The fleet by which the Spanish Armada was defeated, consisted of 176 ships carrying 14,992 men; but of these only thirty-four ships with 6225 men belonged to the Crown. In the last twenty-five years of the reign of Elizabeth, the Royal Navy was almost doubled. The annual expense amounted to £30,000.

Her personal exertions.

Encourages her Nobility to enter the Navy.

James I.

(8.) James I. was not negligent of the Navy, in the former part of his reign, expending £50,000 annually on it, exclusive of timber amounting to £36,000, yearly obtained from the Royal forests. According to Sir Walter Raleigh, it was the practice at this time to build ships by contract. In 1609 Commissions were appointed to rectify many abuses which had insensibly crept into the Navy. In 1610 the Prince was built, of 64 guns and 1400 tons burthen, being the largest ship

Large ship constructed.

* Woolwich is called the Mother Dock by Camden.

† In 1650, there was no mast house or dry dock, nor above 100 shipwrights in this Dock-yard. The first dry dock was formed in 1655.

Naval Architecture.

hitherto constructed in England. "This Royal ship was double built, and most sumptuously adorned within and without, with all manner of curious carving, painting, and rich gilding, being in all respects the greatest and goodliest ship that ever was built in England; and this glorious ship the King gave unto his son Henry Prince of Wales.* The great workmaster in building this ship was Mr. Phineas Pett, sometime Master of Arts of Emanuel College in Cambridge."† In 1619, we find a reference made to the Wardens and Assistants of the Shipwrights' Company, respecting the survey of ships at Deptford; and in the Naval Minutes of Mr. Pepys it is observed, that "the Shipwrights' Hall did anciently view and approve of the draught of the ships that were to be built for the King, and to survey them in the building."‡ In 1620 the King in his Speech to the Parliament affirmed, that £20,000 a year had been saved in the Naval department; and in 1623 the ordinary expenses of the fleet were reduced from about £54,000 a year to £30,000. At the death of King James, the Navy consisted of thirty-three ships, measuring 19,400 tons, proving that an augmentation of the dimensions of ships had taken place.

Shipwrights' Company.

Improvements.

(9.) Sir Walter Raleigh in his Discourse on the invention of shipping, and on the improvements that had been made therein in the reigns of Elizabeth and James, remarks, that "in my own time the shape of our English ships hath been greatly bettered. It is not long since," he continues, "the striking of the topmast hath been devised. Together with the chain-pump, we have lately added the bonnet and drabler. (Sails.) To the courses we have devised studding sails, sprit sails, and top sails. The weighing of anchors by the capstan is also new. We have fallen into consideration of the length of cables,§ and by it we resist the malice of the greatest winds that can blow. We have, also, raised our second decks." These different inventions seem to mark an era of active mechanical improvement.

Charles I. Sovereign of the Seas built.

(10.) Thirteen years after Charles I. ascended the throne, a fleet of sixty sail was equipped. Before the Civil War broke out, the King built at Woolwich a ship called the Sovereign of the Seas. Of this "famous vessel," it was said that "she measured 128 feet or thereabouts, by the keel, her main breadth 48 feet, and in height, from the bottom of the keel to the top of her lantern, 76 feet." It is mentioned of her, as a circumstance worthy of note, that "she bore five lanterns, the biggest of which would hold ten persons upright." That she had also "three flush decks, a forecastle, half-deck, quarterdeck, and roundhouse. Her lower decks had thirty ports for cannon and demi-cannon; middle tier thirty for culverines and demi-cannon; third tier twenty-six for other ordnance, forecastle twelve, and two halfdecks have thirteen or fourteen ports, more within board, for murdering pieces, besides ten pieces of chase ordnance forward, and ten right aft, and many loopholes in the cabins for musket-shot. She hath two galleries besides, and all of most curious carved work, and all the sides of the ship carved with trophies of artillery and types of honour, as well belonging to sea as land, with symbols appertaining to Navigation; also their two Sacred Majesties' badges of honour; arms with several angels holding their letters in compartments, all which works are gilded over, and no other colour but gold and black. Upon the stern-head a Cupid, or child bridling a lion; upon the bulk-head, right forward, stand six statues in sundry postures; these figures represent Concilium, Cura, Conamen, Vis, Virtus, Victoria. Upon the hawsers of the water are four figures, Jupiter, Mars, Neptune, Eolus; on the stern Victory in the midst of a frontispiece; upon the beak-head sitteth King Edgar on horseback, trampling on seven Kings."*

This ship occasioned complaints against Ship-money.

(11.) To this vessel, the largest that ever had been built in England, and said to have been designed only for splendour and magnificence, some have attributed those loud complaints against Ship-money, which marked this Monarch's eventful reign. By building the Sovereign of the Seas it is, however, admitted that Charles rendered a great service to the Navy, by setting the example of increased dimensions, to which all the successes of the English over the Dutch in 1653 were ascribed. In the year 1633 the Navy consisted of fifty ships,† measuring 23,695 tons, carrying 1430 guns, and manned by 9470 men. On the breaking out of the Rebellion in 1641, the number was reduced to forty-two ships, with a burthen of 22,411 tons. Prince Rupert quitted the Kingdom in 1648 with twenty-five ships, none of which ever returned. It has been said that Cromwell could command at the beginning of his usurpation only fourteen ships of war, some of which carried but 40 guns. The first frigate was built in 1649, by Mr. Peter Pett, for a privateer for the Earl of Warwick. Mr. Pett adopted the idea from a French frigate he had seen in the Thames.‡

State of Royal Navy.

Commonwealth. Exertions of Cromwell.

(12.) The vigorous exertions of Cromwell raised the Navy, however, in six years, to 157 ships, carrying 4390 guns and 21,910 seamen, exclusive of the guns and men for four ships then building. Of these, forty-six were foreign built, mostly captured in the Dutch

* It is mentioned as a remarkable circumstance, that the Prince went at three o'clock in the morning to her launching, and named it after his own dignity.

† A circumstance worthy of notice here is, that Mr. Pett, in 1613, remarked, that he "began to victual all the shipwrights and workmen employed."

‡ Mr. Pett was elected and sworn Master of the Shipwrights' Company in April 1606, on which occasion, he says, they kept a feast with a great number of their friends, at the King's Head, in New Fish-Street; and by the new Charter, granted in 1612 for incorporating the Shipwrights of England, he was also ordained the first Master.

§ The cables before this time are said to have been only 78 fathoms long; at the present time they are 101 fathoms long.

* "On the 14th of May, 1635," says Mr. Pett, "I was commanded by His Majesty to hasten into the North, to provide and prepare the frame-timber, plank, and tree-nails for the great new ship at Woolwich. I left my sons to see the moulds and other necessaries shipped in a Newcastleman, hired on purpose to transport our provisions and workmen to Newcastle. The frame, as it was got ready, was shipped and sent in Colliers from Newcastle and Sunderland. The 21st December, 1635 we laid the keel in the dock. She was launched 13th October, 1637, and named the Sovereign of the Seas."

Engravings were made of this ship by Payne, on two plates, joined, 3 feet long, and 2 feet 2 inches high. The original picture is said to have been painted by Vandevelde.

In the list of the King's ships for 1633, the armament of the Prince Royal is distinguished by an *odd* number, namely 55 guns.

† At the present moment, exactly two hundred years after the date specified above, in a time of profound Peace, and when no thought of reductions have been made, the Navy consists of 574 ships.

‡ It would appear from Mr. Pett's monument, in St. Nicholas Church, Deptford, that he was the *inventor* of frigates; this, however, was not the case.

War. During the reign of Charles I. the length of the keel began to be regarded as an element proper to be entered in the official lists; but at the period now under review, the breadth and depth also were inserted. In the list for 1652 we find a 100-gun ship first mentioned, and, singularly enough, called the Sovereign. The length of her keel was 127 feet, breadth 46 feet 6 inches, depth 19 feet 4 inches, and tonnage 1141 tons.*

(13.) Cromwell was so sensible of the respect paid by foreign States to the Naval power of this Country, that, instead of reducing his Navy at the conclusion of the War in 1654, he ordered all the ships to be repaired and put into good condition; he also ordered new ones to be built, and the storehouses and magazines to be replenished as in a time of the greatest danger. Sixty ships were either built or building between 1646 and 1653; and the pay of the sailors was raised from 19*s.* to 24*s.* a month. Estimates for the maintenance and support of the Navy were for the first time laid before Parliament, and the Protector obtained an annual grant of £400,000 for that purpose. During the short and feeble Administration of Cromwell's son, the Navy, it is probable, somewhat declined, the funds being diverted to various other purposes.

Charles II.

(14.) There seems some diversity of opinion respecting the actual amount of the Navy at the time of the Restoration. According to some authorities the whole fleet consisted but of sixty-five ships and vessels of all sizes. Mr. Derrick, however, is inclined to believe the actual amount to have been 162 ships and vessels, with a tonnage (as stated in *Columna Rostrata*, p. 251) of 62,594 tons. In the second Dutch War in February, 1665, it is known the English fleet at sea, and ready for sea, consisted of 114 sail, besides fire-ships and ketches.

Ability of Charles for Naval affairs.

(15.) According to Mr. Pepys, King Charles II. "possessed a transcendent mystery in all maritime affairs." For the first ten years of his reign he was undoubtedly very intent on augmenting our Naval power. He nominated the Duke of York Lord High Admiral; and, by the advice of Mr. Pepys, a Committee was appointed, over which the Duke presided, Mr. Pepys acting as Secretary. The powers formerly granted to the Admiralty and Navy Board were recalled, the Lord High Admiral undertaking the supreme management, with the aid of three new Commissioners, the Comptroller, the Surveyor, and the Clerk of the Acts. Seventy-six ships of the line, stored for six months, were called into active sea pay, besides merchantmen, and a numerous train of ketches, smacks, yachts, &c., with more than 12,000 seamen. At this time, also, there were thirty new ships building, and an abundance of Naval stores.

Construction of two-deck ships.

(16.) In 1663 and 1664 a stimulus was given to our ship-builders by the Dutch and French having built ships of two decks, carrying from 60 to 70 guns, capable of stowing four months' provisions, and having their lower guns four feet above the water. The English frigates at this time were what was then called "Dunkirk built," narrow and sharp vessels, and hence incapable of carrying their guns little more than three feet above the water, and only ten weeks' provisions. Sir Anthony Deane, a keen observer of Naval affairs, and the most accomplished ship-builder at that time in England, endeavoured to correct these defects, by causing two ships to be built capable of carrying six months' provisions, and having their guns 4½ feet above the water.

Charge for the Navy.

(17.) From 1660* to 1670 the charge of the Navy, according to the Lord Keeper Bridgman, had never amounted to less than £500,000 a year. It is remarkable, however, that, in 1665, Lord Clarendon told the Parliament that the Naval and Military stores were entirely exhausted. This is one among many instances of the conflicting testimonies met with in the Public Accounts of the Country, of which our own day is not without examples.

Extravagance of Charles.

(18.) In 1673 the Duke resigned his high office, and from that time until May 1679, the affairs of the Admiralty were managed by the King himself. The vicious habits of this Monarch wasted in dissipation those sums which ought to have been employed in maintaining the Navy; and so sensible was the Parliament of this, that £300,000 was not voted for the Naval service in 1675, without making particular restrictions respecting the appropriation of the money. In 1677, also, £586,000, voted for the building of thirty ships, was subjected to like injunctions. From 1672 to 1684, the affairs of the Navy were managed by a Commission, but so badly were they conducted, that the Naval force at sea had declined to twenty-two ships, none of which were larger than a fourth-rate; whilst the vessels in harbour were totally unfit for service, and falling rapidly into decay. Several of the ships had been reported by the Navy Board to be in danger of sinking at their moorings. The magazines of stores were also reduced to less than £5000 value. Sir Anthony Deane, one of the Commissioners of the Navy, resigned in 1680 or 1681, foreseeing the condition to which the Navy would be reduced. In 1684 the Duke resumed the management of Naval affairs, assisted by the able advice of Mr. Pepys, but the ships continued to decline till the King's decease.

Navy managed by a Commission.

James II.

(19.) It is remarkable, however, and the circumstance ought to operate as a salutary caution in every after Age, that the power and energy of the Duke could not arrest this declension; nor for a whole year after he had become King, could he, with the whole weight of his new authority, check the progressive decay. He resolved therefore to suspend all the ordinary modes by which the business of the Navy had been conducted by the Navy Board, and to call into his aid other persons, on whose experience and industry he could rely. These he joined to a select number of the old Commissioners, in effecting his work of reformation. A part of these members, six in number, was required to sit constantly at the Board, and among them was the able and conscientious Sir Anthony Deane. Three members of the Board superintended the Dock-yards at Chatham, Portsmouth, and Woolwich, and the remainder, with the aid of Lord Falkland, were occupied in adjusting the accounts. Of these Commissioners, Mr. Pepys has remarked, "That they were men possessing a practised knowledge of every part of the works and methods of the Navy, both at the Board and in the Yards; a general mastery in the business of accounts, vigour of mind, and improved industry and integrity;" qualities, we would add, which, in every Age, cannot but be of the first importance to the public service.

* In the list of the Navy for 1651, the armament of the Revolution was distinguished by an *odd* number, *viz.* 85 guns.

* In 1660 the Dutch gave his Majesty a yacht called the Mary. This is the earliest time at which the name Yacht is to be found in our Naval records.

Inquiry into decay of the Navy.

(20.) The first inquiry of the new Commissioners was into the rapid decay of the thirty ships voted to be built in 1677. Some of these vessels were completed the following year, but others not until 1682; and it appeared that their decay did not result so much from the haste with which they had been built, as from the omission of the necessary and ordinary precautions for preserving them. The labours of the Commissioners were so entirely satisfactory, that on the close of the Commission on the 12th of October, 1688, there remained only three ships to be examined of the whole number originally proposed to be repaired. Added to this, stores for eight months instead of six were left in the magazines, disposed in the most admirable order, and ready to be applied to the proper ships.

Arrangements of stores.

The value of the stores so laid apart for each particular ship, together with those on board the ships at sea, amounted to above £280,000. The Commissioners also left in store a further reserve of wood, hemp, pitch, tar, rosin, canvass, iron, and oil, of above £100,000 value; and more new magazines were created in the course of this time than had ever existed before.

Improved condition of the Navy.

Thus the Navy was raised from its feeble and abject state, to a degree of prosperity unparalleled in any previous period of its history. Among other prudent regulations, the Commissioners abolished the irregular supplies of stores which the boatswains and carpenters of ships had hitherto controlled, and fixed one uniform establishment of sea-stores for a ship of each rate. On the abdication of King James, the Royal Navy consisted of 173 ships, having a burthen of 101,892 tons, mounting 6930 guns, and carrying 42,003 men.

William and Mary.

(21.) The Revolution of 1688, which happily accomplished so many important changes, left the code of Naval regulations established by the Commissioners in the preceding reign unaltered. The actors in that important scene wisely left untouched a system which had produced so many important results.

Several large ships built.

Accordingly, an Act was passed in the second year of the reign of William and Mary, for building seventeen ships of 1100 tons each, and carrying 80 guns; three of 1050 tons, and carrying 70 guns each; and ten of 900 tons each, carrying 60 guns, making thirty ships in the whole. The first-mentioned ships had three decks, which mode of construction continued till the War of 1756.

Dock-yards.

In the following year money was voted for a Dock-yard at Plymouth, and also for building additional dry and wet docks at Portsmouth. In 1693, with a view of creating an abundant stock of Naval stores, the sum of £1,926,516 was granted to their Majesties, together with £23,106 for finishing the Naval yard at Plymouth, also £10,908 for building four bomb-vessels, and £68,400 for constructing eight 40-gun ships.

Infernal machines.

About this time, vessels called Machines or Infernals were first employed as fire-ships; their inventor is said to have been M. Meesters. Advice-boats, so called officially, are said to have been employed for the first time in 1692, before the Battle of La Hogue, in order to gain intelligence of what was taking place at Brest.

(22.) At the accession of King William, the Royal Navy consisted of 173 ships, admeasuring 101,892 tons; and at his death it had augmented to 272 ships, with a tonnage of 159,020 tons, the increase being more than one-half, both as to the number and the tonnage of ships.

Anne.

(23.) In the early part of the reign of Queen Anne, the Country was visited by a most desolating storm.* The Navy suffered a great loss, and the House of Commons with the greatest promptitude addressed her Majesty, desiring her to give immediate directions for repairing it, and for building such "capital" ships as she thought fit.

Desolating storm.

Orders were accordingly given to that effect; but it is somewhat remarkable, observes Mr. Derrick, that no money was directly voted by the House in this reign for the building of ships, though in November 1705 a sum was granted for ordnance stores, and carriages for eight new ships, built in lieu of part of those lost in the great storm.

Navy very popular.

The Navy at this time was exceedingly popular, and the many disasters it met with served as a plausible ground for augmenting it. The seamen of the Royal Navy were particularly encouraged, the utmost care being taken of the sick and wounded, and prize-money being speedily paid: regulations which came home to the generous hearts of the sailors, and inspired them with new ardour in their Country's cause. The earnestness of the House of Lords in favour of the well-being of the Navy may be gathered from the following extract of an Address of that body in March 1707:

"*It is a most undoubted maxim, that the honour, security, and wealth of this Kingdom does depend upon the protection and encouragement of Trade, and the improving and right managing its Naval strength. Other nations, who were formerly great and powerful at sea, have, by negligence and mismanagement, lost their Trade, and have seen their maritime power entirely ruined. Therefore we do in the most earnest manner beseech your Majesty, that the sea affairs may always be your first and most peculiar care.*"

At the time of the Queen's death, in 1714, the Royal Navy consisted of 247 ships, bearing 167,219 tons.

George I. Survey of stores.

(24.) In 1715, the year following the accession of George I., a general survey was made of all the stores in the different Dock-yards, which were distributed as follows:

At Deptford	£90,514
Woolwich............	60,174
Chatham............	186,855
Sheerness............	35,216
Portsmouth	182,076
Plymouth............	109,833
Total ...	£664,728

From 1715 to 1721 inclusive, the sum of £1,052,395 was voted for extraordinary repairs and the rebuilding of ships. From 31st of March, 1713, to 31st of December, 1721, there were either built or rebuilt thirty-four ships of the line, three of which carried 100 guns, and twenty-five ships of 40 guns and under. In 1719 new dimensions were established for several classes of ships. The Navy on the whole declined in this reign in a small

* This storm was the most tremendous ever known in the History of the World. It began about the middle of November, and did not reach its greatest height until the morning of the 27th. The Eddystone Lighthouse was blown down at this time. A General Fast was appointed in consequence of the storm. The Queen issued a Proclamation, ordering that all the widows and families of such officers and seamen as had perished by the storm in her Majesty's service, should be entitled to her bounty in the same manner as if they had been actually killed in battle. De Foe, the author of *Robinson Crusoe*, was suffering in Newgate at this time, and composed the *Storm*, being a collection of the most remarkable casualties which happened in this great tempest.

Naval Architecture.

degree, and at the death of the King consisted of the following ships:

Rates or Classes.	Guns.	Number.	Burthen in Tons.
1st	100	7	12,945
2d	90	13	20,125
3d	80	16	21,122
„	70	24	26,836
4th	60	18	16,925
„	50	46	33,829
Ships of the line		124	131,782
Of 40 guns and under		109	39,080
		233	170,862

Notwithstanding the decrease of number, there is still an increase of tonnage, showing that a gradual augmentation of magnitude was insensibly taking place.

George II.

(25.) George II. ascended the throne in 1728, and on the 31st of July of that year, another general survey of stores was made in the several Dock-yards, and the total amount found to be £636,756. For the last six years of the preceding reign, no money was voted for the building and repairs of ships, and the same omission took place during the first and second years of this reign. A ten years' Peace had seemed to render any grant unnecessary.

General survey of stores.

Alteration of ships' guns.

(26.) In 1743, the establishment of ships' guns was altered by order of the King and Council;* and in the succeeding year all prizes taken by his Majesty's ships were declared by the King's Proclamation to be the property of the captors for the time to come.

(27.) In 1744 or 1745, general complaints were made that our ships were not built of sufficient strength, nor their guns carried sufficiently high above the water. They were also said to be very crank, and their weight of metal inferior to those of the enemy, whose batteries were said to be "always open." The Lords Commissioners of the Admiralty, therefore, gave directions to the flag officers, the Surveyor of the Navy, and the master shipwrights of the Dock-yards to prepare a scheme of dimensions and scantlings, and also a draught for a ship of each class; and from these draughts and plans the elements then judged to be most correct were deduced. The

Scheme of dimensions and scantlings.

ships built according to this establishment were found to carry their guns well, and acquired the name of stiff ships; but they were said to be "fully formed" in their after-part. In the War of 1756 some further improvements in the draughts were made, and also a further augmentation of dimensions. The following Table will show the progressive additions made to the Navy during this reign:*

Date.	Ships of the line.	Ships of 40 guns and upwards.	Total.
December 1st, 1730. .	124	114	238
January 1st, 1739 . . .	124	104	228
June 25th, 1742.	125	146	271
December 31st, 1744 .	128	174	302
May 26th, 1748.	140	199	339
January 1st, 1750 . . .	126	156	282
January 1st, 1756 . . .	142	178	320

George III.

(28.) The reign of George III. was destined to see our Naval power rise to unparalleled splendour. At the accession of that upright and conscientious Monarch, on the 25th of October, 1760, the Royal Navy consisted of 127 sail of the line having a burthen of 182,829 tons, and 285 ships of 50 guns and upwards, with a tonnage of 138,275 tons. In the War of 1762 twenty-six sail of the line and eighty-two smaller ships and vessels were built in the merchants yards. Twenty-four sail of the line and twelve smaller ships also were launched in the King's yards between the declaration of War in 1756 and the proclamation of Peace in 1763. According to Beatson, forty-two sail of the line, French and Spanish, together with sixty-nine vessels of 50 guns and under, were either taken or destroyed by the English during that War. Of these, twenty-one sail of the line were added to our Navy.

State of the Navy.

(29.) During this War a resolution was wisely adopted

---

* In the proposition of the Lords Commissioners of the Admiralty for the foregoing establishment, they mention that "since the year 1733, but especially since 1st January, 1740, the dimensions of ships of your Majesty's Navy have been much increased. We do therefore humbly propose that the number and nature of guns directed by your Majesty's Order in Council of 31st January, 1733, may be established on such ships of your Royal Navy as have been ordered to be built or rebuilt since 1st January, 1740, or shall be hereafter built or rebuilt, with this exception, that whereas the ships of 50 guns are now built of such large dimensions that they can conveniently carry 22 guns of 24-pounders upon the lower deck, and as many of 12-pounders upon the upper deck, with 4 guns of 6-pounders upon the quarterdeck, and 2 guns of 6-pounders upon the forecastle, the same may be established upon them, instead of those proposed in the year 1733."

By the draughts established for building ships in 1745, those of 64 and 58 guns had port-holes for 70 and 60 guns as follows:

	64 to carry 70.	58 to carry 60.
Lower deck..........	26	24
Upper deck	28	26
Quarterdeck	12	8
Forecastle	4	2
	70	60

These establishments of guns, and the various changes which they have undergone in different periods of our Naval History, are well worthy of the attention of him who aims at a general and comprehensive view of this important subject.

* A Naval uniform was first established in 1748 by George II., and, according to Mr. Locker, resulted from a Club of sea officers, who met every Sunday evening at Will's Coffee-house in Scotland Yard, for the purpose of watching over their rights and privileges; and who determined among other matters, "that a uniform dress was useful and necessary for the commissioned officers, agreeable to the practice of other nations. A Committee was hence appointed to wait upon the Duke of Bedford and the Admiralty, and ask, if their Lordships approve, that they will be pleased to introduce it to his Majesty."

When it was determined to establish the uniform, Mr. Forbes, then Admiral of the Fleet, was summoned to attend the Duke of Bedford, and being introduced into an apartment surrounded with various dresses, his opinion was asked as to the most appropriate. The Admiral said, red and blue, or blue and red, as these are our national colours. "No," replied his Grace; "the King has determined otherwise. For having seen *my* Duchess riding in the Park a few days ago, in a habit of blue faced with white, the dress took the fancy of his Majesty, who has appointed it for the uniform of the Royal Navy."

Before 1748, Mr. Locker remarks, "every man dressed as seemed good in his own eyes. Some of the crack Captains carried it so far as to have a special uniform for their own ships. My late gallant father, who went to sea in 1746, used to tell us, that Captain Windham, and all the officers of the Kent of 70 guns, in which he embarked, wore grey and silver, faced with scarlet! Such foppery, however, at that period, was not unfrequently combined with check shirts and petticoat trowsers."

"In the Hall at Greenwich may be seen," continues Mr. Locker, "every variety of cut and complexion of dress. Nottingham, Raleigh, and Torrington expand their dignities in courtly costume Lawson, Harman, and Monk frown in buff belts and jerkins. Sandwich, Munden, and Benbow shine forth in armour; while Rooke, and Russell, and Shovell, the heroes of a softer Age, are clothed in crimson and Lincoln green, surmounted with the flowing wig, which then distinguished alike the men of the robe and of the sword."

New scale of ships.

of not building any more 80-gun ships with three decks, or any 70 or 60-gun ships. Ships of 74 and 64 guns on two decks were built instead of those of 80 guns, and 50-gun ships with a roundhouse, for the accommodation of flag officers in time of Peace, instead of ships of 60 guns. The first 74 and 64-gun ships that were built proved too small for their weight of metal, but those constructed towards the latter part of the War were of larger dimensions. In 1766 very great improvements were made in Plymouth and Portsmouth Dock-yards.

(30.) In the armament which took place in 1770, in consequence of the dispute with Spain respecting the Falkland Islands, a large proportion of the ships ordered to be fitted for sea were found very defective; and had a War of long continuance taken place, the most serious consequences might have ensued. An insufficient number of shipwrights in the Dock-yards, together with an improper limitation of their working hours, seemed to have been the cause.

(31.) At the commencement of the American War in 1775, we had 131 ships of the line and 209 vessels of 50 guns and under. The Navy was augmented with every possible rapidity, particularly with frigates, sloops, and other small vessels.

Zealous efforts of the Court of Directors.

(32.) In 1779, the Court of Directors of the East India Company passed a resolution to present three ships of 74 guns to the Crown.* The Naval force continued to receive very rapid augmentations, as well by captures from the enemy as by building. No exertions, indeed, it has been remarked, could possibly be deemed extravagant, when the activity of our enemies was considered.† The supplies voted by Parliament very far exceeded those of any former period. At the signing of the Preliminaries of Peace in 1783, there were 174 ships of the line, and vessels of 56 guns and under amounting to 443, the total tonnage being 500,781 tons. Thus it appears, that the Navy at this period exceeded what it was at the end of the War in 1762 by thirty-three sail of the line, having a tonnage of 71,070 tons, and of other vessels by 152, with a tonnage of 86,405; making a total increase of 185 ships, and a total augmentation of tonnage amounting to 157,475 tons. The French, Spanish, and Dutch ships taken or destroyed by the English in the course of this War amounted to twenty-six sail of the line, and sixty-one vessels of 54 guns and under, besides sloops and vessels of other kinds.

Great power of Navy at this time.

Dimensions of ships increased.

(33.) During this War, almost every class of ships of 44 guns and under was considerably increased in dimensions, when any new ones were ordered to be built; and at the latter end of 1778, the greatest part of the second-rates were established with eight additional guns for their quarterdecks, thereby making them 98-gun ships.

Ships in ordinary.

(34.) In June 1783, several masters in the Navy were appointed to superintend the state of the ships in ordinary at Chatham, Sheerness, Portsmouth, and Plymouth. In the following year, the Navy Board wisely ordered that every individual ship built or put into good condition, should in future have a large proportion of the principal parts of her furniture and stores in readiness, and duly arranged in store for her, so that the remainder might not require more time to provide than the necessary period for her equipment would admit, however short that time might be. In addition to this important regulation, another originated with Lord Barham, of creating an establishment of stores of a great variety of kinds, as general magazines at each Dock-yard, and also at the other Naval stations, both at home and abroad. This arrangement resulted probably from the difficulties experienced in procuring some articles, and the high prices paid for others during the War; and the same, doubtless, must have been the case, in a greater or less degree, in most of the preceding Wars. Since that time the advantages of the plan have been abundantly proved. The following Table furnishes an account of the value of the principal articles in store at the several Dock-yards on the 31st of December, 1792

	Unappropriated.	Appropriated.	Total.
Deptford . .	£180,388	£38,170	£218,558
Woolwich .	164,406	25,144	189,550
Chatham . .	213,305	164,999	378,304
Sheerness .	50,699	21,108	71,807
Portsmouth	317,414	131,210	448,624
Plymouth .	326,880	179,259	506,139
Total .	£1,253,092	£559,890	£1,812,982

On January 1st, 1802, three months after the signing of the Preliminaries of Peace, the unappropriated stores remaining in the magazines at the several Dock-yards were as follows:

Deptford	£308,093
Woolwich.	600,656
Chatham	423,697
Sheerness.	99,400
Portsmouth	567,243
Plymouth	611,819
Total	£2,610,908

On comparing the value of the stores in the several Dock-yards at different periods, it will appear, that the magazines have been increased in a greater ratio than the ships, great as the increase in the latter has been. The confederacy among the Northern Powers, and the embargo in the Russian ports, in November 1800, would have been attended with the most serious consequences, had not the magazines been previously well stored. This instance alone proves the wisdom of the plan. Old ships were selected in this year, and afterwards fitted for the reception of ships' companies and stores, during the time ships were in dock refitting. Previously to this arrangment, serviceable ships, not in good condition, were made use of for the purpose, which did them considerable injury. These were denominated Receiving ships.

Task and job work.

(35.) Task work was introduced into the Dock-yards in 1775, and job work in 1784. The former of these

* We are no friends to the privateering system, regarding it as little better than a licensed system of plunder and fraud, but it would be improper to omit in an historical account like the present, a notice of the extraordinary exertions made by the traders of Liverpool at this period. According to Mr. Chalmers, (see his *Estimate of the Comparative Strength of Great Britain,*) that port alone fitted out, at the beginning of the War with France, between the 26th of July, 1778, and the 17th of April in the following year, 120 privateers, each armed with from 10 to 30 guns, but mostly with from 14 to 20. From an accurate list, containing the name and appointment of each vessel, it appears that these privateers measured 30 787 tons, carrying 1986 tons, and 8754 men.

† The War with Spain commenced in 1779, and with Holland in 1780. In August, 1779, the combined fleets of France and Spain, consisting of sixty-six sail of the line, besides frigates, &c. entered the Channel, and appeared off Plymouth. This formidable fleet was a proof of the immense activity of our enemies in augmenting their Naval force during the Peace, and particularly so when we consider their losses during the preceding War.

terms applies to new work, and the latter to repairs or old work. These plans were adopted in order to accelerate the work in the Dock-yards, and particularly with regard to the shipwrights. When task work was first introduced, notwithstanding the plan appeared very advantageous to the workmen, it was resisted by the shipwrights; and the reason assigned was that when any piece of timber proved defective or unfit for use, after having been fashioned to its intended shape, no compensation was provided for the workmanship performed. It was at length directed that the workmen should be paid a daily rate of wages for the time that might be lost in the conversion of unsound materials, and in the performance of some extra works; it was likewise ordered that they should have assistance in the heavy work of getting in the beams. Notwithstanding these concessions, the shipwrights persisted in their refusal to work by task until the year 1788, when it is said to have been adopted at their own solicitation. Equal reluctance was displayed by the men in adopting job work, but it was finally carried into effect in the same year as piece work. The first ship repaired by job in Plymouth yard was the Gibraltar of 80 guns.

Dispute respecting adoption.

Magazines.

(36) In 1787, it was directed that ships lying up in good condition should have the works of their magazines and store-rooms completed, in order to be the sooner ready for sea. In 1790, two ships of 110 guns each were ordered to be built, of the burthen of 2332 tons. These ships were to have 32-pounders on their main decks.

110-gun ships built.

(37.) To give an idea of the prodigious activity which prevailed in our Dock-yards, when the circumstances of the French Revolution compelled us to arm, it may be stated that on the 1st of December, 1792, there were only twelve line of battle ships in actual commission as fighting ships, but by the 1st of September, 1793, that number was augmented to seventy-two.* In like manner, at the former period, there were only thirty ships from 50 to 20 guns each in commission; but at the latter, this number was increased to 104. It was remarked, that no delay arose for want of stores, in consequence of the important measures adopted at the end of the War in 1783

Activity in our Dock-yards at the French [illegible]

(38.) In 1793, two very important improvements took place, *viz.* the lengthening of ships very considerably;† and the giving 44-gun frigates, and those down to 32 guns, four, instead of three-inch bottoms. The object of the first change was with a view of making them sail better; and of the second, to enable them to resist with greater effect any bearing on the ground. At this time, it is said, there was scarcely a class of ship or vessel whose plan of construction was not improved.

Lengthening of ships. Increasing thickness of their bottoms. General improvement of vessels of all kinds.

(39.) In 1794, the Caledonia of 120 guns, and 2602 tons burthen, was ordered to be built, and to carry 32-pounders on her main deck. This ship seems to have communicated an impulse to ship-building; she was built by Sir William Rule.

Ships of 120 guns built.

In 1797, seamen's wages were raised as follows:

Augmentation

	£.	s.	d.		£.	s.	d.	
Able from	1	4	0	to	1	9	6	per month
Ordinary	0	19	0	to	1	3	6	
Landsmen, (a new class)				..	1	2	6	

* Of these, two were of 110 guns, five of 100 guns, twenty-one of 98 and 90 guns. The total tonnage of ships of the line was 234,136 tons.

† The Prince, a 90-gun ship, was taken into dock at Portsmouth, and lengthened 17 feet.

The following Table will show the progressive increase of ships of the line, and of ships of 56 guns and under:

	Jan. 1. 1795.	Jan. 1. 1797.	Jan. 1. 1799.	Oct. 1. 1801.
Ships of the line........	145	161	176	180
Of 56 guns and under. .	454	530	627	684
Total.....	599	691	803	864

Thus the number of ships and vessels at the conclusion of the War in October 1801, exceeded the number at the close of the War in 1783 by 247 sail. On the 1st of August, 1799, the number of ships of the line in commission amounted to 154, which was the maximum at any part of the War. Of the ships belonging to the enemy, and taken or destroyed by the English in the course of the War, there were of the line and down to 54 guns inclusive, 86; of 50 guns 3; of frigates 206; and of sloops and small vessels 275; making a grand total of 570. The English ships taken or destroyed by the enemy, were of the line to 54 guns inclusive, 5; of 50 guns, 1; of frigates 12; and of sloops and small vessels 41; making a total of 59. The conquests of the English were therefore nearly as ten to one when compared with those of the enemy.

Great increase in the number of our ships.

Ships captured from the enemy.

(40.) In 1803, the Country was called on to renew a War which, if it had been tremendous before, was now calculated to unfold with redoubled horrors its awful and desolating effects. On the 15th of May, the Royal Navy consisted of 177 ships of the line, and of 56 guns and under 593, making a total of 770. On the 1st of January 1805, the total amount was 649; and on the 1st of October of the same year there were in commission of the line and to 54 guns inclusive, 121 sail; of frigates 158, and sloops, including hired armed ships and vessels, 416; making a grand total of 698. It was, indeed, a season of the most extraordinary activity, and the most remarkable energies were called into action. From 1808 to 1813 there were seldom less than from 100 to 106 sail of the line, from 130 to 160 frigates, upwards of 200 sloops, besides bombs, gun-brigs, cutters, schooners, &c. in active service. To this enormous service were to be added another 500 sail in ordinary, employed as prison, hospital, and receiving ships, all performing offices tending to make our Naval arm more powerful and efficient. Thus a thousand pendants floated proudly in the wind, the united burthen of the whole amounting to 800,000 or 900,000 tons. Our wide and extended commerce supplied an abundance of prime seamen, and the perpetual activity of our public and private yards served to keep every part of this gigantic machine in the most perfect order. A glorious succession of brilliant victories placed the Naval supremacy of the Country on the most transcendent height; and so well was this superiority maintained, that at the close of the most awful and sanguinary War which History had ever recorded, the accumulated Navies of the whole World bore but a small proportion to ours.

Renewal of the War 1803.

Amount of the Navy in 1803 and 1805.

Enormous fleets in actual commission.

Great number of ships otherwise employed in ordinary.

Brilliant results.

(41.) These great and transcendent exertions were aided by corresponding energies on shore. An entire renovation of the Civil departments of the Navy, and of the mechanical labour in the Dock-yards, served to infuse new life into a system, which, with even all its energies, had become impaired by corrupt systems of management. The period from 1803 marks, indeed, a new era in our existence as a Naval people. The Earl of St. Vincent, who had rendered so great services to his

Entire renovation of the Civil departments of the Navy.

Great services of the Earl of St. Vincent, in reforming the Civil departments of the Navy.

Country by the victory obtained near the Cape which gave to him his glorious title, not only had the merit of training up a body of first-rate seamen, and introducing the most effective modes of discipline at sea, but he also directed his keen and scrutinizing eye into the Dock-yards at home and abroad. It was evident to every Naval man, that there was an extravagant expenditure and an improper mode of conducting the public business in these great establishments; but it required a mind of a fearless cast and of great and comprehensive powers to grapple with its multiplied details. Such a man was Lord St. Vincent.* Commissioners were appointed to inquire into our great Naval establishments; and these able men† entered on their important task with a boldness and decision which at once removed every suspicion of partiality, and neutralized every claim of private friendship. They acted as public men ought at all times to act, with no other object in view than the public good.

Commissioners appointed to inquire into abuses.

Subjects of the Reports

(42.) The different Reports of the Commissioners related to the Naval Dock-yards abroad, which it had been long suspected were nurseries of extravagance and fraud; to the peculations practised on those splendid foundations of charity which the piety and patriotism of former Ages had established for the relief of our gallant seamen; to the supply of blocks for the Navy; to the cooper's contract; to the subject of prize agency; to the Sixpenny Office; to the frauds in labour at our Dock-yards,‡ and to the reporting ships as sound that were unsound;* to our Naval Hospitals; to the Victualling department; to the receipt and expenditure of stores; to the Treasurer of the Navy, which led to the resignation and impeachment of Lord Melville; to the issue of Navy bills, and to the purchase of hemp, masts, and fir, for the use of the Navy. All these Reports reflect the greatest honour on their distinguished authors. It required no little perseverance, no little fortitude to pursue in all their detail the great questions which they embraced. Wrapped up in official forms, concealed in all the mystery which men interested in perpetuating frauds know so well how to assume, it required a keen and penetrating eye to detect the evils which a long continuance of bad government had introduced. It was, indeed, time to look into our public departments, and when the service of the Country required so enormous an expenditure, to see that it was properly applied. There is a natural tendency in every thing human to become corrupt; and it is the part of a wise and good Government, by rigid and wholesome checks, to endeavour by every means to prevent it. According to Dr. Colquhoun, the different Naval charges during the reign of George III. amounted to £116,641,862. What a field for peculation and fraud must this enormous sum have afforded! In the single year 1813, there was expended for Naval purposes alone £21,212,011 sterling.

Immense Naval expenditure during the reign of George III.

Imperfect instructions issued to the Dock-yards.

(43.) It may be proper to remark with regard to those Reports which relate more particularly to the Dock-yards, that many abuses doubtless arose from the imperfect regulations and the heterogeneous orders from time to time issued to the officers of the different yards The regulations addressed to the officers in the XVIIth Century, may have been, and probably were, suitable to the then confined state of the Navy; but as the Navy increased, additional instructions were framed to suit its new and more enlarged conditions. These

* The Writer of this Essay, living in the neighbourhood of a Naval arsenal, when quite a boy, remembers well the deep tone of indignation manifested by almost every one connected with our Dock yards, when these important and necessary inquiries were begun.

† The Commissioners were, Vice-Admiral Sir Charles M. Pole, Bart, Ewan Law, Esq., John Ford, Esq., Captain Henry Nicholls, R N, and William Mackworth Praed, Esq.

‡ Much of our successful advancement in the mechanical arts resolves itself into a question of wages. It appears that in our Dock yards, the daily pay of the artificers, when first established in the XVIIth Century, must have been very considerable for the times The settled change in the expense and mode of living, however, had reduced that pay below what was necessary for their support, and had removed every objection to an increase, arising from an expectation of a return to the former state of things. When a rate of pay becomes insufficient from causes of a sudden and extraordinary nature, temporary means may be resorted to; but when the cause is permanent, temporizing expedients, so far from being useful, generally end in conceding to importunity more than, if granted at a proper time, would have been gratefully received. It appears from the history of our Dock-yards that many extraordinary anomalies have existed in this important particular at different times Previous to 1793, the shipwrights were limited in their earnings to 2*s*. 8½*d* a day in Winter, and 3*s* 1*d* in Summer, *the time of their being employed being, in both cases, the common hours of the yard* In 1793, on the contrary, their earnings were limited, both for Summer and Winter, to the constant sum of 4*s*. 2*d*. per day, the time when they were employed being increased, by their being required to work their dinner-time, by which an hour and a half additional labour was obtained. But the common hours of work in Winter being fewer than those in Summer, the pay should not have been the same in both seasons In 1794, the same limit of earnings was continued, but the additional hour and a half was conceded. This gave an increase of 10*d*. a day in Summer, and 1*s* 5½*d* a day in Winter, beyond the limit of prices prior to 1793 One of the inferences deducible from these absurd arrangements is, that the workmen must have been considered as capable of earning, by the same exertions, as much in a less time as in a greater. The Commissioners remark, "that the men could only be made to appear to have earned their full stint in these unequal times of labour, by falsifying the accounts; or, as the officers were left to propose such prices as they might think fit, by their increasing the valuation of the different articles in the same proportion as the Navy Board increased the rate of working, or stint of earnings." The case of the Antelope of 50 guns, built at Sheerness at this time, afforded a practical example of the truth of this position. On a comparison of the expense attending the performance of the works by job, with the sums which would have been allowed if the same works had been performed by task, there appears to have been an excess upon the articles performed by job of nearly one half.

* Every one knows the unfortunate catastrophe that befell the excellent and worthy Flinders. Having entered, as he informs us, the great Gulf of Carpentaria, and surveyed all the projecting capes, creeks, bays, and islands of its Eastern side, it became necessary to calk the ship, when to his great mortification,—and to an ardent mind like his, what mortification could be greater?—the officers reported her to be in such a rotten state as to be wholly unfit to encounter bad weather, and that should she get on shore under any unfavourable circumstances, she must immediately go to pieces; that she was too far gone to bear heaving down on any account; but that in fine weather, and barring accident, she *might* run six months longer. Flinders however determined to complete the survey of the Gulf, and at the end of three months, he was compelled to make another examination of his vessel at Port Jackson. Here the Investigator was found to be so excessively rotten, that she was reported "not worth repairing in any Country, and impossible, in this Country, to be put in a state fit for going to sea." She was, therefore, condemned and sold.

Who, knowing the sufferings and indignities Flinders afterwards endured at Port Louis, but will place them to the account of the careless and ignorant officers who surveyed the "North Country built ship of 334 tons" in which he sailed? The Governor, De Caen, treated him as an impostor and a spy; seized all his books, papers, and charts; placed him in a miserable chamber containing only a truckle bed without curtains, a small table, and a rush-bottomed chair, with a grenadier in the room to watch over him. In this miserable way this virtuous and excellent officer remained a close prisoner for nearly four months.

were often found to be contradictory, and in many instances the regulations of the different yards disagreed. Earl Howe and Sir Charles Middleton, when they presided at the Admiralty and Navy Boards saw the necessity of revising and digesting these orders, and the latter had made some progress in so useful a work when he quitted office. Hence the Commissioners recommended that no time should be lost in reviewing what had been done, in order that the Civil departments of the Navy might, in future, be conducted with order, regularity, and economy.

Consequence of depriving the master shipwrights, &c. of taking apprentices.

(44.) The depriving, by successive regulations, the master shipwrights, their assistants, the foremen, and the quartermen of the privilege of taking apprentices, soon led to some remarkable results. Parents no longer thought of sending sons to the Dock-yards who had received any tincture of a liberal education, since the only persons they could be bound to in order to learn the practice of ship-building were the working shipwrights; and even some regulations were made respecting the privilege these men enjoyed, which had a tendency to lessen the attention they might be expected to give to instruction. The natural result hence followed, that only the very lowest class of the people, and those least likely to have received any education, were induced to enter the Dock-yards. In such a state of things it was hardly to be imagined the superior officers of the yard would feel any interest in the advancement of young men. Accordingly we find in the Report of Naval Revision, "that not one of the apprentices entered in this way had been brought into the mould lofts," where the drawings for ships are executed, and where something like an approach to the principles of the Art might be attained. The reason assigned was, none of the apprentices could be found of suitable education;* so that being without the means of improvement in the Dock-yards, they could not but remain in the same state of ignorance as when their apprenticeship began. It can scarcely be necessary to add," continue the Commissioners, "that unless this part of the present system shall be altered, even good working shipwrights will hardly be found in our Dock-yards; and it would be vain to expect order and regularity in the conduct of the business, accuracy in the accounts, or professional skill in those who must, at no great distance of time, come, of course, to be intrusted with the management of every thing respecting the construction of the ships by which this Country is to be defended." Supposing this course to have been persisted in, it could not but have led to the most disastrous results; it was, in fact, cutting up the very roots of our Naval greatness. "In looking forward," say the Commissioners, "unless some means be taken for the improvement of the education of apprentices, we must not expect a succession of officers or artificers equal to those now in the Dock-yards."

Establishment of School of Naval Architecture.

(45.) This important Report led to the establishment of the School of Naval Architecture at Portsmouth in 1811. It was conceived by the Commissioners that by training up a race of men devoted to Naval Architecture, both in its theory and practice, under the eye of an able Mathematician, important results might fairly be anticipated; and the Government, entering with earnestness and liberality into their views, endeavoured, by every imaginable means, to promote them. The Journals of the day announced that the whole was open to competition. At the head of the Institution was placed the Rev. Dr. Inman, a learned Mathematician, who, in his early days, had obtained the highest honours at Cambridge, and evinced an eminent capability of conducting an undertaking of this kind. During the seven years the students remained at the establishment they were called upon to pursue the study of Geometry in an enlarged way, to carry its beautiful and refined principles into Natural Philosophy, and to enter on the Differential and Integral Calculus. The theory of Naval Architecture was diligently studied, some of the best Continental writers on the subject being diligently read. At the same time the practice of the Art was entered on, and the young men were taught the laying off of ships, and how to prepare every necessary drawing. An excellent practical shipwright (Mr. Fincham) instructed them in all the details of labour at the dock-side; and the adze and the saw were required to be worked with the ardour and spirit of the humblest operative. The object was to make them good theoretical and practical shipwrights, and the Country has a right to expect that they should be so. Of the students admitted at the different public examinations from 1811 to 1822, some have retired from the service, some have died, and twenty-six remain, three of whom have become builders' assistants, others are foremen in the different Dock-yards, and seven remained unprovided for in 1833.*

* These are the official words of the Report. We cannot but observe, however, that prejudice *must* have had some share, perhaps a large share, in this opinion. It can hardly be supposed but that among the mass of apprentices in our Dock-yards, some might have been found worthy of the distinction of entering a mould loft. "Genius," says Washington Irving, "delights in hatching her offspring in by-places;" but it requires the eye of genius frequently to discover it. Had the experiment been tried of a public competition, after suitable notice, among these uneducated youths, there can be little doubt but many would have been found capable of promoting their own intellectual advancement. The great principle of competition remains to be tried in our public departments. The advantages resulting from such a state of things would be immense. At the moment at which we are writing this Note nothing but a dull and melancholy depression is to be met with in the working departments of our Dock-yards.

* We throw into a note a brief notice of the Ordonnance of Charles X. of France, dated 28th March, 1830, relative to the organization of the Royal corps of Naval engineers. (*Géne Maritime.*) It is to consist of the following:—

		Francs.
One inspector-general..................	each	15,000.
Five directors of Naval constructions.......	at Brest, Toulon, and Rochfort.	8000.
	at Cherbourg and Lorient	7000
Ten engineers of the first class		5000
Twelve engineers of the second class		4000
Twelve sub-engineers of the first class		3000
Twelve sub-engineers of the second class ..		2400
Five sub-engineers of the third class		2000

in all 57; and of a number of cadets, to be regulated according to the demands of the service, each to receive annually 1200 francs.

These cadets are to be taken from among those students of the Polytechnic School who are declared worthy of admission into the public services. They are then to pursue for two years at the Port of L'Orient, (under the direction of an engineer of the first or second class, to be nominated by the Minister of Marine,) a complete course of the application of theory to Naval Architecture; to exercise themselves in making drawings of ships of war, and in the details of their masting, sails, fittings, and equipment; to make calculations of displacement, of stability, of the centre of gravity, and all others relative to the theory of Naval Architecture; to investigate the nature of steam-engines and all other machines which may be useful either in the arsenals, or on board ships of war; to design ornamental work, and to study the English Language.

At the expiration of two years, the cadets will be subjected to

Naval Architecture.

Advantages resulting from the employment of such men as Brunel at our Naval stations.

(46.) It must not be omitted in closing this very brief review of the eventful reign of George III., that we owe to the liberal views of Earl Spencer, who at one time presided at the Admiralty, the devotion of the great talents of Bentham, Brunel, and Barrallier to the public service. That distinguished Nobleman encouraged these eminent men to undertake works most beneficial to the Navy. Before this period, while steam-engines and other powerful machines were abundantly applied in all our manufactories, by a singular fatality they had been wholly neglected in our Dock-yards. Instead of our Naval establishments being schools of practical science, and affording the most perfect patterns of mechanical skill, a dark and imperfect system prevailed of employing only the unaided strength of men and horses. Steam, with all its multiplied applications and powers, was entirely unknown, and docks were pumped, and the heaviest weights raised by mere animal strength. Such men as Brunel cannot but impart new light and intelligence wherever they appear. Born to invent and command, they are destined at every step to add new trophies to the intellectual dominion of Man. Matter assumes new forms, and with the wand of a magician, they seem to rule the elements with it. Hence the unrivalled block-machinery at Portsmouth, exhibiting the most perfect mechanical refinements, and challenging the admiration of the whole world. Had other men, possessing only perhaps a small portion of Brunel's transcendent powers, been encouraged to turn their attention more particularly to Naval Architecture, who could estimate the triumphs that might have accompanied them? It is impossible for a mind accustomed to the higher walks of human thought, to descend to a lower walk of inquiry, without the latter receiving some benefit from the power thus applied to it. At this moment we fear the amount of really *active* practical Science in our Dock-yards is but small.'

Naval Architecture.

George IV.

(47.) Our limits will not permit us to give an account of many important particulars relating to the Navy and Naval improvement which occurred during the closing years of the reign of George III., and that of George IV. The Peace brought with it the repose so much desired; and public men as well as private individuals, no longer having their minds excited by the feverish anxieties of War, had leisure to turn their thoughts to many objects of great importance to our maritime power. Hence many salutary regulations, and the adoption of many important changes, which time has proved to be beneficial, and which it must be our desire to see further perfected and improved. We may refer in this way in terms of the strongest commendation to the labours of Sir Robert Seppings, which will be particularly elucidated in other chapters. The labours of that eminent man, and the immense benefits he conferred on our marine, can never be forgotten, either by the lover of mechanical improvement or the lover of his Country. The introduction of chain cables by Captain Brown has deprived a lee-shore of many of its terrors. Iron tanks, by augmenting the supply of fresh water, have contributed very greatly to the comfort of seamen, and by enabling our fleets to keep longer at sea, have increased their efficiency in a prodigious degree. The Truscott pump has removed the dangerous necessity of getting water-casks on deck; and the abolition of the practice of sending King's stores from the Dock-yards in boats belonging to ships of war, required, as they often were, to do so in tempestuous weather, has preserved the lives of many gallant seamen. The powder also, which by an ancient and dangerous practice was sent on board unfilled, is now received into a ship ready prepared for action. The store-rooms, which at one time exhibited scenes of the greatest irregularity and disorder, present at the present time every thing that can gratify the lover of Naval discipline and order. The wings, or intervals, between the ship's sides on the orlop decks, so necessary to the vigilance and labours of the carpenter during action, and which in seasons gone by were filled with the midshipmen's and quarter-master's hammocks and chests, bags and lanterns,—a receptacle of filth and foul air,—are now kept perfectly clear and clean, as they ought to be.

Improvements of Sir Robert Seppings and others.

Other improvements in the service.

Improvements in signals.

(48.) The science of signals, which has contributed so mainly to our brilliant victories, has also in these latter times been greatly improved. A system which enabled the immortal Nelson to communicate to his whole fleet in the short space of three minutes his splendid and memorable sentence "ENGLAND EXPECTS EVERY MAN TO DO HIS DUTY," cannot but be advantageous. The ships which sailed for India in 1780, possessed merely flags for indicating the most ordinary messages, such as seeing the land, discovering a strange ship, or calling an officer on board. In the War of 1793, Lord Howe's system of tabular signals was employed; and from that time their advance was rapid. In 1795, signal-posts were established on the South coast of England, to indicate the approach of the enemy's cruisers, and to give timely information to our seamen. The land telegraph, connecting the Admiralty with all the sea-ports, produced a celerity of movement quite unknown in former times. The semaphore at present employed in this way was adopted from the French. The sea telegraph was the invention of Sir Home Popham.

an examination in the various branches of instruction they have received. Those who are qualified are immediately to receive the appointment of sub-engineers of the third class, their seniority of rank being fixed by the results of the examination. The sub-engineers of the first and second classes cannot be promoted to the first class until they have made a voyage of at least one year. Specific rules also are laid down respecting the employments of these sub-engineers when on shipboard; these are the details of stowage, the arrangement and effects of the means employed in moving the top masts, top-gallant mast and yards, and also in furling and unfurling the sails, on the working of anchors, on the effects which the shocks of waves and the motions of pitching and rolling have on the combination of the various parts of the structure: and, generally, on every subject relative to Naval construction. They shall keep watch on deck with the most experienced officer on board having charge of a watch.

The following Table of comparative rank is worthy of attentive consideration.

Officers of Naval Engineers.	Officers of the Navy.	Officers of Naval Administration.
Inspector general.	Rear-admiral.	
Director of Naval Constructions.	After the Rear-admirals and before the Post-captains.	Commissary-general.
Engineer, 1st class.	Post-captain (Capitaine de vaisseau.)	Commissary of the Navy.
Ditto, 2d class.	Commander (Capitaine de frégate.)	
Sub-engineer, 1st class.	Lieutenant.	Sub-commissary, 1st class.
Ditto, 2d class.		Ditto, 2d class.
Ditto, 3d class.	Mate. (Enseigne de vaisseau.)	Principal clerks.
Cadet.	Midshipman.	

Uniforms are established for the Naval engineers

Naval Architecture.

William IV.

Abolition of Navy and Victualling Boards.

(49.) By an Act passed in the second year of the reign of King William IV, a very remarkable change took place in the administration of the Civil departments of the Navy. The offices or departments of the principal officers and Commissioners of the Navy, and of the Commissioners for victualling the Navy, and for the Care of Sick and Wounded Seamen, were entirely abolished; the powers and authorities heretofore vested in these Boards being transferred to the Admiralty.

Change of officers at the Dock-yards.

By the same Act, the duties hitherto performed by Commissioners at the several Dock-yards and other Naval and Victualling establishments at home and abroad, are in future to be executed by officers called Superintendents; the Commissioners of the Admiralty and the Superintendents being empowered to administer oaths and execute the duties of Justices.

One general account opened at the Bank for the Navy.

With regard to the important article of expenditure, it was enacted that one general account should be opened at the Bank of England for Naval services; and annual accounts be made up and certified, together with rigid annual inspections of all monies remaining with the Treasurer of the Navy, his cashiers and clerks. Monthly accounts also are to be furnished from the several Dock-yards. The Admiralty also is enjoined to make up an annual account of expenditure, under the heads of service specified in the Appropriation Act, the Commissioners of Audit being empowered to examine the same, and to lay a copy thereof before Parliament.

Officers connected with the Civil departments of the Navy.

(50.) At the present time the various officers connected with the Civil departments of the Navy are the following: seven Commissioners for executing the office of Lord High Admiral of the United Kingdom of Great Britain and Ireland, with two Secretaries, and senior and junior clerks. Several principal officers, *viz.* a Surveyor of the Navy, an Accountant-General, a Storekeeper General, a Comptroller of the Victualling of the Navy and of the Transport Service, Physician of the Navy, and a Civil Architect. Connected with the Navy Pay Office, there is a Treasurer of the Navy, with various subordinate officers relating to the Wages, the Bill, Ticket, and Allotment branch, the Navy Bill branch, the Victualling Bill branch, &c.

Navy estimates.

Estimate for 1833–1834.

(51.) The Navy estimates, in future, are to be arranged as follows:

Nos. Required for the Service of the year 1833–1834.

Nos.			£	s.	d.
1. Wages	of seamen and marines	£871,550	955,220	0	0
	of the ordinary, yard, craft, &c.	83,670			
2. Victuals	of seamen and marines	103,650	438,004	0	0
	Abate "Old stores"	7,830			
		395,820			
	of the ordinary, yard, craft, &c.	12,184			
3. Admiralty Office			101,070	0	0
4. Navy Pay Office			21,725	0	0
5. Scientific branch*			22,109	0	0
6. His Majesty's establishments at home			114,970	0	0
7. His Majesty's establishments abroad			25,122	0	0
8. Wages to artificers, &c. employed in His Majesty's establishments at home*			438,426	0	0
9. Wages to artificers, &c. employed in His Majesty's establishments abroad			26,905	0	0
10. Naval stores, &c. for the building and repair of ships, docks, wharfs, &c.†			123,600	0	0
11. New works and improvements in the yards, &c.			63,700	0	0
12. Medicines and medical stores			31,500	0	0
13. Miscellaneous services			50,380	0	0
Total for the effective service			£2,713 131	0	0
14. Half-pay to officers of the Navy and Royal Marines‡			871,858	0	0
15. Military pensions and allowances			533,103	0	0
16. Civil pensions and allowances			220,342	0	0
Total for the Naval service			£4,339,031	0	0
For the Service of other Departments of Government.					
17. Army and Ordnance departments (conveyance of troops, &c.)			200,800	0	0
— Colonial department			—	—	—
18. Home department (convict service)			118,300	0	0
Grand Total			£4,658,131	0	0

* It is worth while to give in a note an abstract of the scientific branch:

	£	s.	d.
Royal Naval College and School for Naval Architecture			
Royal Observatory	2,750	1	0
Observatory at the Cape of Good Hope	1,020	0	0
Nautical Almanack	4,160	0	0
Chronometers	1,700	0	0
Rewards, experiments, &c.	1,000	0	0
Hydrographical department	11,199	12	0
Extra pay for exploring the Quorra and Southern Continent	259	4	0
Libraries and Museum at Haslar and Plymouth Hospital	1,100	0	0
Gratuity to Mr. Grant for his Biscuit Manufactory	2,000	0	0
Total	£22,109	0	0

* The wages to artificers and labourers *at home* to those *abroad*, are to each other in about the ratio of *sixteen* to *one*.

Dutch Auction.

† The mode of disposing of old ships and stores in his Majesty's Dock-yards by what is called Dutch Auction, deserves an explanation. The article to be sold is put up by an officer at some price previously fixed on. He then progressively lowers the sum, until some one says *mine*, when it is knocked down to the speaker, or he becomes the purchaser. Certain conditions are in most cases entered into by the purchaser, in the case of ships, that they are to be broken up within twelve months of the day of sale. This was the case with the San Antonio, Phaeton, and Virginia in the succeeding Table. Copper bolts marked with the King's broad arrow ↑ are also to be returned, the purchaser receiving a fair value for them in return. The following Table will give the particulars of a sale of several ships of war, on the 11th of July, 1827, at Somerset House, in presence of three Commissioners of the Navy.

Name of ship.	Guns or class.	Tonnage.	Place where the ship was lying.	Price at which it was put up by the Commissioners.	Price at which it was sold.
Pheasant	22	365	Deptford	£1100	[illegible]
Bann	Sloop	466	Chatham	[illegible]	[illegible]
Belette	Brig	386	Ditto	[illegible]	[illegible]
San Antonio	74	1700	Portsmouth	[illegible]	[illegible]
Phaeton	46	941	Ditto	[illegible]	[illegible]
Argus	Brig	387	Ditto	[illegible]	2000
[illegible]	Cutter	145	Ditto	[illegible]	[illegible]
Scout	Brig	382	Ditto	1560	1010
Quail	Cutter	82	Ditto	700	110
Virginia	38	1066	Plymouth	3500	[illegible]
Petrel	Sloop	365	Ditto	1160	[illegible]

‡ The original Orders in Council bestowing half-pay on Naval officers, required them to reside in the sea ports, and to assist in fitting out ships. Half-pay was hence a payment for service performed in time of Peace.

Admirals and Captains were first appointed Generals and Colonels of Marines in 1759, soon after the Battle between Hawke and Conflans. The first General of Marines was Admiral Boscawen, and the first Colonel Sir P. Brett.

The Naval sinecure offices amount only to the annual sum of £7750: and every name in the subjoined list is distinguished by the most brilliant services. It is the honour of being associated with the great commanders who have held these posts, more than the actual emoluments arising from them, that render them

Naval Architecture.

This account, it should be remembered, has reference to a period of profound Peace, of rigid and unrelenting economy, and when every means are taken to reduce all the public establishments to a minimum of expense.*

Our limits will not permit us to give more than a brief analysis of this important statement, referring to the Navy Estimates themselves for more detailed information.

Naval establishments at home.

(52.) The establishments at home connected with the Navy consist of NAVAL YARDS, VICTUALLING ESTABLISHMENTS, MEDICAL ESTABLISHMENTS, TRANSPORT ESTABLISHMENTS, MARINE BARRACKS, AND MARINE INFIRMARIES.

(53.) The Naval yards are at Deptford, Woolwich, Chatham, Sheerness, Portsmouth, Plymouth, Pembroke, Deal, North Yarmouth, and Kingstown. The Victualling establishments are those of Deptford, Sheerness, Portsmouth, Plymouth, Haulbowline, Brixham, Staddon Point, Milor, Deal, and Dover. The Medical establishments are Haslar and Plymouth. The Transport establishments are Deptford, Portsmouth, Leith, and the Cove of Cork. Marine barracks are found at Woolwich, Chatham, Portsmouth, and Plymouth; at which places also are the Marine infirmaries.* The total sum voted for the financial year

---

objects of honourable ambition. It is worthy also of record, that *no offices* whatever are executed by deputy in the Navy.

Description of Office.	Salary, Pay, and Allowances received. £. s. d.	Date of Appointment.	Rank of Officer holding the Office.	Where employed.	How long employed in active service. Years.
Vice-admiral of England..	469 5 8 a year.	30 Jan. 1833.	Sir Edward Thornbrough, Admiral of the Red, G.C.B.	In various parts of the world afloat	49½
Rear-admiral of England..	370 4 3	24 ditto.	Sir George Martin, Admiral of the White, G.C.B.	Ditto.	33
General of Marines	1728 15 0	13 Feb. 1832.	Lord De Saumarez, Admiral of the Red, G.C.B.	Ditto.	47
Lieut.-General of Marines..	1383 0 0	23 June, 1830.	Sir William Sidney Smith, Admiral of the White, K.C.B.	Ditto.	21
Major-General of Marines..	1037 5 0	5 April, 1821.	Right Hon. Sir George Cockburn, Vice-Admiral of the Red, G.C.B.	Ditto.	29
Colonel of Marines	690 9 2	22 July, 1830.	William Skipsey, Captain Royal Navy	Ditto.	34

Ditto ditto	690 9 2	Ditto.	Hon. Duncan Pleydell Bouverie, Captain Royal Navy.	Ditto.	23

Admiralty, 27th February, 1833.

French Marine Budget.

* The following is an abstract of the Budget of the French Minister of Marine and Colonial Affairs for the year 1829

	Francs.
Salary of the Minister, of Directors and subdirectors, Prefects of Marine, officers on shore, *équipages de ligne* on shore, Marine artillery, Naval engineers, Officers having charge of Commissariat, Chaplains, Medical staff, Professors in Navigation Schools, of persons employed in felling timber in French Guianne, Storekeepers, &c. Officers of Hulks, and persons employed in the Royal Founderies..........	11,791,876
Pay of General Staff at sea, of the crew of one ship of the line, ditto of the crews of 127 vessels, containing 12,410 men, and expense of clothing the *équipages de ligne*, fuel for the *troupes de la marine*, barracks, &c.	7,863,800
Expense of Marine hospitals for sick mariners	1,181,500
Ditto of provisions	6,834,500
Pay of workmen, expense of ship-building, materials, and artillery	23,621,300
Expense of docks, &c.	3,800,000
Expense of the galley slaves	312,400
Miscellaneous expenses	692,000
Expenses of the Army and Navy in the colonies....	6,000,000
Total ..	63,109,976

In 1823 a Royal Ordonnance was promulgated for establishing a distinct body of seamen to serve on ship-board or in the Naval arsenals, to be called *équipage de ligne*. This body is divided into separate corps, each corps being composed of a permanent Staff of ten persons, and of four companies of 150 men each.

All the Officers of the Royal Navy, from the rank of *Enseigne de vaisseau* to that of *Capitaine de frégate* inclusive, must be employed in the *équipage de ligne*, and serve in it two years successively, unless they receive orders to the contrary from the Minister of Marine. Every seaman belonging to the *équipages de ligne* must be instructed and rendered fit to perform all duties whatever which relate to the manoeuvring, piloting, serving at the guns, or repairing of a vessel, together with the manual exercise as a Marine on ship-board or in the Naval arsenal. The men of the *équipages de ligne* are employed in all vessels from a ship of the line to a 16 gun brig inclusive. See Goldsmith's *Statistics of France*, London, 1832.

Navy disbursements of the United States

The amount disbursed annually in the Navy establishments of the United States is about three millions and a quarter of dollars, a considerable portion of which is devoted to its gradual improvement, by the accumulation of stores, the creation of dry docks, and the building of additional vessels.

The following is an account of the principal elements of expenditure for 1829.

	Dollars.	Cts.
Pay and subsistence of the Navy afloat ...	1,160,068	09
Ditto ditto shore stations	161,830	26
Pay of superintendents, artificers, &c.......	62,222	56
Provisions	461,636	83
Medicines and hospital stores.............	25,772	60
Repairs and improvements of Navy yards ..	148,989	09
Ordnance and ordnance stores............	26,262	61
Gradual improvement of the Navy	444,395	98
Repairs of vessels.......................	470,945	68
Labourers and fuel for engine	1,660	45
Pay and subsistence of the Marine corps	117,329	19

These various sums, together with other different expenses, form a grand total amount of 3,308,745 dollars 47 cents.

* It was once the practice to employ officers of the Army in the Marine service, and the Marines themselves were privates of the Army. In all the great actions before Cromwell's time, and during the time of the usurper, soldiers were constantly embarked as Marines.

Naval Architecture.

1833—34 for the pay of the various officers connected with these establishments, taxes, and other incidental expenses amounted to £114,970.

Naval establishments abroad.

(54.) His Majesty's establishments abroad consist of NAVAL YARDS, VICTUALLING ESTABLISHMENTS, MEDICAL ESTABLISHMENTS, and TRANSPORT ESTABLISHMENTS.

(55.) The Naval yards are at Gibraltar, Malta, Canada, (Kingston and Montreal,) Halifax, Newfoundland, Bermuda, Antigua, Jamaica, Sierra Leone, and Fernando Po, Cape of Good Hope, and Trincomalee. The Victualling establishments are at Gibraltar, Malta, Halifax, Bermuda, Jamaica, Bahamas, Barbadoes, Ascension, Sierra Leone, Fernando Po, Cape of Good Hope, and Rio de Janeiro. The Medical establishments are found at Malta, Halifax, Bermuda, Jamaica, and Cape of Good Hope. A single Transport establishment exists at Gibraltar. The total sum voted for the financial year 1833—34 was £23,422.

Officers of Portsmouth Dock-yard.

(56.) We can only give a brief enumeration of the officers of one of each of these establishments. Taking Portsmouth Dock-yard as the first and most important at home, we in the first place remark, that it is governed by an Admiral Superintendent, the other principal yards having only a Captain Superintendent presiding over them.* The officers next in rank are a master attendant and assistant; a master shipwright and two assistants; a storekeeper, store receiver, surgeon and assistant, a chaplain, timber converter, boatswain, and warden, together with twenty-seven clerks. Also masters for the smiths, sail-makers, riggers, and rope-makers; ten foremen of the yard; two conductors of the wood and metal mills; foremen for the millwrights, metal mills, rope-makers, and smiths; two assistant timber converters, and twelve measurers.

Victualling establishment at Deptford.

(57.) Of the Victualling establishments, we select Deptford, which has a Captain Superintendent, a storekeeper, a master attendant of the wharf and assistant; a surgeon and assistant; fourteen clerks; a master cooper, master miller, and master baker; a warden; two foremen of coopers, and four foremen of stores, together with an engineer.

Plymouth Hospital.

(58.) Of the Medical establishments we take that of Plymouth Hospital, which is governed by a Captain Superintendent, who attends, also, to the Victualling establishment, assisted by two lieutenants; there is also attached a physician, a surgeon, an agent and steward, a dispenser, a chaplain, three clerks, and four hospital mates.

Marine barracks.

(59.) To the Marine barracks are attached a barrack master, barrack sergeant, and barrack clerk; and to the Marine infirmaries belong a surgeon and two assistants, a purveyor, a chaplain, and a quarter-master.

Naval yard at Malta.

(60.) Of the establishments abroad, we take the Naval yard at Malta, which has an Admiral Superintendent, a Naval storekeeper, a master attendant, master shipwright, clerks, boatswain, and foreman of shipwrights. To the Victualling establishment at the same place there is attached an agent victualler and clerks; and to the Hospital, a surgeon, dispenser, hospital mate, chaplain, and clerk.†

* The Superintendents of the Dock-yards were formerly Civil situations, the persons filling them being styled Commissioners. They are not at this time so considered. The alteration took place on the 1st of June, 1832.

† Where there is no Superintendent, the Commander in Chief is, as far as may be in his power, to see that every officer punctually obeys the orders and instructions he shall have received from the Lords Commissioners of the Admiralty. The Commander in Chief in such a case is to conform to the established rules and general practice of the Navy. He is also to receive from the storekeeper, and every other person intrusted with the charge of money, three general statements of their respective accounts quarterly, which he is to examine and certify.

Wages of shipwrights, &c. at the several Dock-yards.

(61.) For the wages of shipwrights, other artificers, and labourers employed in the Dock-yards at home, during 1833—34, there were paid the following sums:

Woolwich	£53,500
Chatham	65,500
Sheerness	28,000
Portsmouth	108,400
Plymouth	113,000
Pembroke	21,000
Deal } Haulbowline }	600
Making a total of	£390,000

Important question of labour.

(62.) The question of labour in the Dock-yards has occupied much of the attention of the Admiralty and of the late Navy Board. While the Country loudly called for retrenchment, the members of these Boards were anxious to effect it with the least possible privation to individuals. In January 1830, it was resolved that the payment of chip money should cease, and that no more men or apprentices should be entered in the yard, in lieu of others dying or discharged, until the number should be reduced to 6000, the number to be preserved during Peace. As soon as the number should be brought down to 7000, the men were to be allowed to work the whole of Wednesday, and when reduced to 6500 to work six days in the week. These arrangements prove the anxious desire of the Admiralty for the welfare of the workmen. The following Table will give the total establishments borne on the books of the Dock-yards at home in the years mentioned in it.

Total number of workmen and apprentices.

	Inferior Officers.	Workmen.	Apprentices.	Total.
Jan. 1, 1830 ...	213	7068	648	7929
Jan. 1, 1831 ...	197	6560	633	7390
Jan. 1, 1832 ...	172	6505	524	7201

Great change in the system of labour.

(63.) During the year 1833, however, an entire change of system has taken place in the Dock-yards respecting labour, with the view of economizing the consumption of the public stores. The jobbing, or contract plan hitherto adopted has been abolished, and the men have been placed under an entirely new system of classification.

Abolition of contract work.

The practice of contract work grew out of the necessities of the War, when extra labour was almost daily called for; but the system has been found productive of great public loss. It has been said, and we believe with great truth, that when men are paid according to the quantity of work done, they are not very scrupulous about the conversion of materials, and thus an immense waste of public stores has been the consequence.

Waste of materials.

To remedy this evil, the present Board of Admiralty resolved to return to the old plan of fixed allotted work and daily pay; and there existing no necessity for urgent despatch in time of Peace, the present has been selected as a proper period for effecting a change. At the same time, also, it was resolved that superannuations should be abolished.

(64.) As a curious and important document respect-

Naval Architecture.

ing the distribution of labour in the Dock-yards, and showing the relative importance of the different trades employed in them, we add the following valuable Table drawn up by the Navy Board on the supposition that the workmen were reduced to 6000. We regret that our limits will not permit us to dilate upon this important document.

Table of the distribution of workmen.

Description.	Deptford.	Woolwich.	Chatham.	Sheerness.	Portsmouth.	Plymouth.	Pembroke.	Total.

Of the shipwrights above stated, *viz.* 2500,* a considerable number will be employed as house carpenters, (that description of artificers having been abolished) and in other inferior trades; the object being to retain as many shipwrights as possible at the same expense as persons of those descriptions would be paid in working at their own trades.

Expense of warders, watchmen, &c.

(65.) The annual expense of warders, watchmen, and rounders, in the Dock-yards last adverted to, amounted for 1833 - 34 to £11,676, a great but necessary sum. While this Essay has been passing through the press, an important change has been made. A regular and systematic Police has been established* in the

New system of Police.

* The 2500 shipwrights here alluded to, would complete annually, fit for launching, fifteen 120-gun ships; twenty 80-gun ships; twenty-six seventy fours, thirty-six double-banked frigates of 52 guns, or seventy corvettes of 28 guns.

In the reign of Charles I Mr Phineas Pett speaks of hiring and victualling the shipwrights and calkers, on several occasions, and of their being discharged when the work for which they were hired was performed. The victualling of workmen forms a singular contrast with the customs of the present day It is not known when this practice was given up. It is supposed that there was a small permanent establishment of artificers in each of the existing Dock-yards for ordinary purposes.

In the reign of Queen Anne, the maximum number of shipwrights in the several Dock-yards amounted to 2574, exceeding the number admitted at present to be necessary; the minimum number during that reign was 1678.

In the period from 1744 to 1805 inclusive. the greatest number of shipwrights were employed in 1800, amounting to 3776. The least number was in 1755, amounting to 2305. In 1803 the number was 2878.

* It appears that a Central Board of Police was strongly recommended by the Select Committee of the House of Commons on Finance, in their 28th Report. printed in June 1798. It was then proposed to bring under regulations by licenses, all dealers in old and second-hand ship's stores, old iron, and other stores, and several other dangerous and suspicious trades, the uncontrolled exercise of which, by persons of loose conduct, is known to contribute to the concealment and multiplication of crimes. Dr. Colquhoun, however. remarks in addition, that salutary as this Central Board must certainly be in controlling and checking the Naval plunder, in common with the general delinquency of the whole Country. it would seem indispensably necessary, under circumstances where the moving property is so extensive, and where there exist so many resources and temptations leading to the commission of crimes, to fix on some one person the responsibility of carrying the laws into effect, and of controlling and overawing the various classes of delinquents,

Great plunder formerly in the Dock-yards.

Dock-yards of Chatham and Sheerness, and doubtless will be extended to the other yards. The former history of our Dock-yards is indeed a history of plunder and fraud.* It is true that, in later times, things have been better; but the plunder of several tons of copper, even within the last two years, no traces of which were detected before the metal had reached Birmingham, proves there is still something defective; something which a vigilant Board of Admiralty ought to correct.

Prevention of crime the great principle to be observed.

(66.) We have now before us a printed copy of the Police Instructions, the fundamental principle of which is "*the Prevention of Crime;*" a principle salutary in itself, and calculated, if followed out in all its consequences with energy and effect, to produce the most beneficial results. It does not appear that the arrangements are yet perfect respecting this important change; but the admission of the necessity of a change, the beginning that has been already made in breaking up the old system, the putting new and altered powers into motion, cannot but be advantageous.

Classes and denominations of Royal Navy.

(67.) The Royal Navy is divided into the following classes and denominations.

1. Rated ships, *viz.*

First rate, all three-decked ships.

Second rate, one of his Majesty's yachts, and all two-decked ships of 80 guns and upwards.

Third rate, his Majesty's other yachts, and all ships of 70 guns and less than 80.

Fourth rate, ships of 50 guns, and less than 70.

Fifth rate, ships of 36 guns, and less than 50

Sixth rate, ships of 24 guns, and less than 36.

2. Sloops and bomb vessels.

3. Gun brigs, cutters, schooners, and other small vessels.*

Erroneous system which formerly prevailed.

(68.) These different classes and denominations are doubtless very proper, and experience has proved, that many advantages result from ships of different magnitudes; but there can be no possible reason why ships of the *same* rate should vary so much in size. When Nelson was off Cadiz with seventeen or eighteen sail of the line, he had no less than *seven* different classes of 74-gun ships, each requiring different masts, sails, yards, &c., so that if one ship was disabled, the others could not supply her with appropriate stores. No state of things could possibly be more deplorable than this, and to an acute and sensitive mind like Nelson's, it must have been a source of the deepest regret. In the reign of James I. the classes of ships were, ships royal, great ships, middling ships, small ships, and pinnaces. Ships were first distinguished by rates in the reign of Charles I.

Amount of the Royal Navy on the 1st of October, 1833.

(69.) The Royal Navy on the 1st of October, 1833, consisted of 557 ships of all classes. Of these, fourteen were of 120 guns, five of 110 guns, three of 108 guns, twelve of 84 guns, ten of 80 guns, nine of 78 guns, six of 76 guns, sixty-two of 74 guns, seven of 52 guns, fifteen of 50 guns, sixty-two of 46 guns, twenty of 42 guns, and twenty-two steamers; the remaining ships varying from 30 to 4 guns.†

whose attention is directed to the Dock-yards as a means of obtaining plunder. In the Work on the Police of the Metropolis, we find a section named, *A Local Police for the Dock-yards.*

* Dr. Colquhoun remarks, that the abuses, frauds, and embezzlements are multifarious, and are perpetrated through the medium of a vast variety of agencies, which naturally divide themselves into two distinct branches.

The first relates to frauds committed by the connivance and assistance of clerks, storekeepers, and inferior officers in the Dock-yards, and other repositories, and in ships of war and transports, in receiving and delivering Naval, Victualling, and Ordnance stores; in surveys, in returns of unserviceable stores, in what is called solving of stores, in fraudulent certificates, in the sale of old stores, and innumerable other devices.

The second branch relates to the actual pillage of new and old cordage, bolts of canvass, sails, bunting, twine of all sorts, fearnought and kersey leather and hides, old and new coppers, locks, hinges and bolts, copper bolts and nails in immense quantities, bar iron, old iron, lead and solder, ship's plank, oars, timber of small sizes, blocks, quarterstuff, candles, tallow, oil, paint, pitch, tar, turpentine, varnish, rosin, beer and water casks, iron hoops, biscuit bags, beer, bread, wine, brandy, rum, oil, vinegar, butter, cheese, beef, pork, &c.

Many vessels in the coasting trade, and even ships of foreign nations, it is said, touch at Portsmouth and Plymouth, merely for the purpose of purchasing cheap stores.

The artificers in the Dock-yards, availing themselves of their perquisite of chips, not only commit great frauds, by often cutting up useful timber, and wasting time in doing so; but also in frequently concealing, within their bundles of chips, copper bolts, and other valuable articles, which are removed by their wives and children, (and as has appeared in judicial evidence, by boys retained for the purpose,) and afterwards sold to itinerant Jews, or to the dealers in old iron and stores, who are always to be found in abundance wherever the Dock-yards are situated.

Among the multitude of persons concerned in these fraudulent transactions, some are said to keep men constantly employed in untwisting the cordage for the purpose of removing the King's mark, or coloured straw, which is introduced into it as a check against fraud; while others are, in like manner, employed in cutting the broad arrow out of copper bolts, nails, bar iron, and other articles, on which it is impressed, so as to elude detection.

These remarks are from the Doctor's Work on the Police of the Metropolis, edition 1806, and relate to a time of War. Things are very much mended now, but we decidedly approve of a local Police for the Dock-yards.

* Whenever any of His Majesty's ships or vessels are fitted as steam-vessels, troop-ships, surveying-ships, fire-ships, prison-ships, hospital-ships, store-ships, and victualling-ships, or for any other temporary service, the Lords Commissioners of the Admiralty may assign to them such rate or class, not above a fourth-rate, as they may judge proper.

French Navy in 1831.

† The French Navy in 1831 consisted of the following:—thirty-five ships of the line of three rates, forty frigates of three rates; twenty-three corvettes of from 18 to 32 guns; fifty-seven brigs of from 8 to 20 guns; eight bombs; galliots and cutters, eighteen of 8 guns; forty-one of 4 guns; twelve steam-boats, sixteen armed store-ships, thirty-two armed transports, and two yachts, amounting in all to 284 vessels fit for sea, whether in commission or lying in ordinary. At the same time, also, there were twenty ships of the line and twenty-six frigates building, besides several corvettes, brigs, steam-boats, and store-ships. There were also to be put on the stocks in 1832, three ships of the line, two third-rate frigates, three corvettes, and five steam-boats.

Navy of United States in 1830.

In 1830 the United States' Navy consisted of seven sail of the line, all of which were laid up in ordinary; seven frigates of the first class, of which three were in ordinary and four in commission; three frigates of the second class, of which one was a receiving-ship, one in actual service, and one in ordinary; fifteen sloops, of which two were in ordinary, and the remainder on different foreign stations; seven schooners, of which three were in employ as receiving-ships, one in ordinary, and two in commission. There were also five ships of the line and seven frigates in such a state of forwardness that they could be ready for sea in three months. There are seven Navy yards maintained by the Government in different States of the Union. In the Secretary's Report an allusion is made to the construction of two dry-docks, "seldom rivalled in beauty and solidity." The expenditure on each has been 500,000 dollars. A great progress has been made in constructing buildings for the accommodation of officers of the yards, in storehouses, sheds, wharfs, walls, and shipways. Rope walks also are contemplated. The vessels in ordinary have been covered at most of the yards, to shelter them from sunshine and storms. The purchase of timber and stores under the Act for the gradual increase of the Navy, remaining in the yard, amount to a million and a half. The amount of property on hand for repairs is almost a million. The ordnance, provisions, &c., amount to upwards of a million and a half.

Naval Architecture.

Number of ships in commission

(70.) Of these there were in commission 126, *viz.*, five three-deckers, varying from 104 to 120 guns, eight second and third-rates, varying from 74 to 84 guns; seven fourth-rates of 50 guns; eight fifth-rates, varying from 36 to 46 guns; sixteen sixth-rates, varying from 24 to 28 guns; thirty sloops, varying from 16 to 20 guns; and nineteen 10-gun brigs; the remainder being small vessels carrying from 2 to 8 guns. The sailors required for this force amount to 20,000, and the Marines 9000. The Marines thus amount to nearly half the seamen. In 1793 they amounted to only one-seventh; but in the latter part of the War the proportion rose to considerably more than one-fifth.

Classes of officers in the Royal Navy.

(71.) The Officers of his Majesty's Navy are divided into three classes, *viz.*, Commission officers, Warrant officers, and Petty officers.

The Commission officers are of the undermentioned denominations, and take precedence and rank in the following order:—Flag officers, Commodores, Captains, Commanders, and Lieutenants.*

Warrant officers are of the following denominations, which also represent the order of their respective ranks:—

1. Masters,
2. Secretaries,
3. Physicians,
4. Chaplains,† } To rank with Lieutenants, of the Navy, but to be subordinate to them.
5. Surgeons,
6. Pursers,
7. Mates.
8. Second masters.
9. Assistant-surgeons.
10. Gunners.
11. Boatswains.
12. Carpenters.

The Petty officers arranged according to their ranks are the following:—

1. Schoolmaster.
2. Clerks.
3. Masters at arms.
4. Ship's corporals.

(72.) The following Table contains an analysis of the various classes and denominations of the officers and men for the several rates of our ships, and furnishes a good idea of the beautiful economy that prevails in this great and important particular.

Classes for Distribution of Seizures.	Ranks and Ratings.	First Rate.	Second Rate.	Third Rate.	Fourth Rate.	Fifth Rate.	Sixth Rate.	Sloops. 100 Men, and upwards.	Sloops. Under 100 Men	Bombs	Gun-Brigs, Schooners, and Cutters.

* Relative rank of Officers of the Navy and Army.
1. Admirals of the Fleet with Field-marshals of the Army.
2. Admirals with Generals.
3. Vice-admirals with Lieutenant-generals.
4. Rear-admirals with Major-generals.
5. Commodores with Brigadier-generals.
6. Captains after three years from the dates of their first commissions for rated ships with Colonels.
7. All other Captains with Lieutenant-colonels.
8. Commanders with Majors.
9. Lieutenants with Captains.
10. Masters with Junior Captains.

† It is very gratifying to read the strict and earnest injunctions enforced on the attention of the Chaplain in the Admiralty Instructions respecting his important duties. To instruct, to be attentive, to be very assiduous, are terms applied to all the different branches of his duty; displaying an anxious concern for the religious, moral, and intellectual welfare of all on board.

Distribution of our Naval forces.

(73.) At the present time we have Admirals' flags flying at the Nore, Portsmouth, and Plymouth, in the Mediterranean, the West Indies, Halifax, and Newfoundland, in South America, the East Indies, Lisbon, Cape of Good Hope, and coast of Africa, and on particular service. In all ten Admirals.* These are the present Naval stations. In former Wars, much unpleasant litigation arose among the flag-officers of his Majesty's fleet, in consequence of the limits of the different stations not having been properly defined. Since that time, however, the Admiralty have so marked the boundaries of each command, that any future dispute seems impossible. These limits may be seen in vol. v. of Brenton's *Naval History*, p. 348, &c.

Admirals at present in the Navy List.

(74.) At the present time also there are on the Navy List one Admiral of the fleet, forty-six Admirals, fifty-five Vice-admirals, and sixty-four Rear-admirals.

Their rates of sea-pay and of half-pay *per diem* are the following:—

	Sea-pay.			Half-pay.		
Admiral of the fleet	£6	0	0	£3	3	0
Admiral	5	0	0	2	2	0
Vice-admiral	4	0	0	1	12	6
Rear-admiral or Commodore of the first class, Captain of the fleet	3	0	0	1	5	0*

Post Captains.

(75.) There are also 799 Post Captains, of whom fifty-four are actively employed. Their sea-pay is by the

* In 1812 we had two Admirals' flags flying in the Baltic, one at Leith, one at Yarmouth, four in the Texel and Scheldt, one at the Nore, one in the Downs, one at Portsmouth, one at Plymouth, one Guernsey and Jersey, one in Ireland, three in the Channel fleet; one on the coast of Portugal, seven in the Mediterranean, one at Newfoundland, one at Halifax, one at Jamaica, one at the Leeward Islands, one on the coast of Africa, two in South America, one at the Cape of Good Hope, and one in the East Indies: in all thirty-four.

The duties of a Commander in Chief are twofold—those relating to general service, and to the Civil establishments. They will be found in the Admiralty regulations and instructions and embrace a vast variety of important objects. Frequently a Commander in Chief has to undertake matters of a diplomatic nature, and sometimes he has to act on his own responsibility on circumstances of the greatest moment. This must of course be on foreign stations. The admirable letters of Lord Collingwood show his case with what ability he conducted some of the most delicate and important negotiations. In all the varied duties connected with his extensive command in the Mediterranean, after the Battle of Trafalgar, he showed himself a profound, and provident, and truly English-hearted statesman.

* In the reign of James II. Admirals and Captains of the Navy received only very small pay, but were allowed in addition a certain retinue, and for the men composing it so much a day, with the value of their provisions. Those allowances led to great abuses.

month, and is governed by the rate of the ship they command. A Captain of a first-rate in commission receives £61. 7*s*. 4*d*. per month, and the other rates, down to the fifth, diminish (omitting some trifling fractions) by a common decrement of an eighth part of that sum, thereby giving to the Captain of the last mentioned rate a monthly pay of £30. 13*s*. 8. The Captain of a sixth-rate receives a sixteenth part of £61. 7*s*. 4*d*. less than a Captain of a fifth-rate. It would be curious to know what circumstances led to the determination of these fractional decrements. A different scale of arrangement takes place in the pay of these officers when on half-pay. Each of the first hundred as they stand on the general list of officers in seniority receive 14*s*. 6*d*. a day; each of the next 150 a daily half-pay of 12*s*. 6*d*. and to the remainder 10*s*. 6*d*. per day.*

Commanders.

(76.) Of the Commanders there are 881, of whom 110 are employed on active service. The latter receive an eighth part of £61. 7*s*. 4*d*. (omitting a fraction) less than the Captain of a fifth-rate. Of this class of officers when on half-pay, each of the first 150 on the list receive 10*s*. a day, and the remainder 8*s*. 6*d*.†

By an Order in Council dated 22d February, 1693, the extravagant number of servants previously allowed was abolished, and the officers were allowed a number about equal to the present establishment. This wise and salutary plan, which excluded all profits on servants, and assigned an adequate rate of net pay, was, however, rescinded by Order in Council of 18th April, 1700, which established the following rates of pay, and reestablished the following extravagant number of servants:—

	Pay.			Servants.
Admiral of the fleet	£5	0	0	50
Admiral	3	10	0	30
Vice-admiral	2	10	0	20
Rear-admiral	1	15	0	15

and at these rates the pay of the flag-officers remained for upwards of 100 years. till, by Order in Council of 23d April, 1806, an alteration took place. It was computed in the Appendix to the Order in Council of February, 1693, that the annual saving to the Public on the reduction of the servants, would be on each officer as follows:—

Admiral of the fleet...............	£1014	0	0
Admiral..........................	557	14	0
Vice-admiral......................	304	4	0
Rear-admiral	177	9	0

* The Admiralty instructions to Captains respecting the fitting of ships, their stores and provisions, their books and accounts, their discipline, pilotage, and sick quarters, &c. &c. &c., form a body of knowledge of a most important kind; and we regret that our limits will only permit us thus briefly to allude to them.

† In every sea-port of France, the resort of ships of war, a Maritime Prefect is established, who is generally either a Vice or Rear-admiral. His functions correspond with those of a Port-admiral in England.

	Francs per ann.
The Maritime Prefects receive, when not employed at sea	18,000
Vice-admiral	15,000
Rear-admiral (Contre amiral).............	10,000
Post Captain (Capitaine de vaisseau, 1st class) .	5,000
Captain (Capitaine de vaisseau, 2d class)	4,500
Commander (Capitaine de frégate)	3,500.

When at sea, the officers receive a supplementary pay of one-fifth of the above, besides a daily mess allowance, which varies with the service or station on which they are employed.

The pay and allowances of officers as well as men, and also all payments whatever made on account of the service of the Navy, are subject to a deduction of three per cent. for the support of the sick, and for granting pensions to Naval invalids. There never has existed in France any special asylum for aged or invalid seamen, similar to Greenwich Hospital. It is true, however, Naval invalids, after thirty years' effective service, when supplied with certificates of good character, and supported by high interest, may be admitted into the *Hôtel des Invalides* at Paris; and it is also true that there are special Hospitals for the sick belonging to the Navy, while in service, at Brest, Toulon, Rochefort, L'Orient, and Cherbourg.

(77.) The rates of pay of Post Captains and Commanders for the different rates and sloops and bombs, may be represented by the following series, wherein p denotes the Captain's pay of a first-rate.

p...	Captain of a first-rate.
$\frac{7}{8}\,p$...	of a second-rate.
$\frac{6}{8}\,p$..	of a third-rate.
$\frac{5}{8}\,p$..	of a fourth-rate.
$\frac{4}{8}\,p$...	of a fifth-rate.
$\frac{7}{16}\,p$...	of a sixth-rate.
$\frac{3}{8}\,p$...	commander of sloops and bombs.

(78.) The Lieutenants amount to 3207; 658 of these being on active service. Lieutenants.

(79.) There are 496 Masters, of whom 98 are employed. Masters.

(80.) There are 12 Physicians belonging to the Navy, 712 Surgeons for service, and 318 Assistant Surgeons. 92 Surgeons and 108 Assistant Surgeons are on active service. Physicians. Surgeons.

(81.) The Pursers amount to 635, of whom 89 are on service. Pursers.

(82.) The active list of Chaplains amounts to 37. Chaplains.

(83.) As a proof, also, that the Admiralty are not unmindful of their important duties as regards the qualities of ships, and consequently their improvement, the following series of questions forms a part of the instructions issued to every officer on his taking the command of a ship.

Naval Architecture.

Character of the Ship after a trial of months.

- How many days of the following articles does she stow for her complement of men? .... Provisions. Bread .... Spirits ...
- Does she ride easy at her anchors? ....
- How many degrees does she heel, with a fresh breeze, under single-reefed top-sails and top-gallant sails? ....
- How many degrees does she heel, with a strong breeze, under double-reefed top-sails, without top-gallant sails?.........................
- How does she carry her lee-ports?...........
- Does she roll easy or uneasy in the trough of the sea? ....
- Does she pitch easy?.........................
- Is she, generally speaking, an easy or uneasy ship? ....
- How does she in general carry her helm? ... with all sails set?.......... / with treble-reefed top-sails and courses? ....
- How does she steer? ....
- How does she stay?.........................
- How does she wear? ....
- Is she weatherly or leewardly, compared with other ships?..........................
- How does she behave lying-to?...............
- She has run per hour by the log with as much wind as she could safely carry this sail to — Knots. Fathoms
  - Close-hauled with smooth water. Under whole or single-reefed top-sails and top-gallant sails .....
  - Close-hauled with smooth water. Under double-reefed top-sails....
  - Close-hauled with a head sea. Under double-reefed top-sails and top-gallant sails
  - Close-hauled with a head sea. Under close-reefed top-sails and courses ....
  - Large, under all sail that could with propriety be set ....
  - Before the wind under similar circumstances.................
- What is her best point of sailing compared with other ships?.....................
- Comparative rate of sailing compared with other ships?..............................
- Is she, generally speaking, a well-built and strong ship, or does she, on the contrary, show any symptoms of weakness?........
- Remarks, stating the grounds of such of the present answers as may differ from those of the last Report, and any other observations tending to form an accurate judgment on the qualities of the ship ....

Captain. Master. Carpenter.

There must therefore be an immense body of valuable knowledge now buried in the innumerable returns that have been made to these questions, and from which the hand of industry might deduce some important results.

Experimental squadrons.

(84.) Since the Peace, many keen and angry discussions have taken place respecting the best mode of building our ships of war; and several experimental squadrons have been sent out, composed of ships built by different projectors. Nothing decisive, however, seems to have resulted from these attempts; and Naval Architecture, considered as a Science, seems now to remain nearly as it did before. New plans have also been adopted for the internal fittings of our men of war; and in the case of the Thunderer, recently commissioned by the gallant Captain Wise, no cabins are permitted on the two gun-decks, the whole space being left free for fighting.

Appointment of a new Surveyor of the Navy.

(85.) The appointment of a new Surveyor of the Navy has led to the greatest changes in the forms and dimensions of ships hitherto attempted. The vessels in which Nelson and Duncan fought can hardly be compared with the magnificent vessels now building in our Dock-yards. The following Tables will furnish an account of their principal elements.

Dimensions of the new ships.

Naval Architecture.

(87.) Such are the elements of some of the ships built or building in our Dock-yards, under the new state of things; and others on a still larger scale are spoken of. The Americans, acting on a principle of policy, taught us the necessity of augmenting the dimensions of our ships of war; and the vessels which our Dock-yards now produce, prove that the lesson has not been taught in vain. The increased expense arising from augmented dimensions, however, ought to render us cautious not to carry this principle beyond its necessary and proper limits.

Tactics. Undoubted claims of Clerk.

(88.) The great problem of breaking an enemy's line, owes its origin entirely to Mr. Clerk of Eldin. That splendid discovery ranks with many other great events which influence the fate of nations, and impart a new aspect to the affairs of men. By its ready and admirable adoption on the 12th of April, 1782, by Rodney, it led to the most decisive and brilliant results; and other commanders, following up the same great principle, have likewise gained from it an unfading renown. It must have been a source of the purest pleasure to Mr. Clerk, to have witnessed the complete success of the theory on which he had so long and so deeply meditated; and, moreover, to have received as its richest fruits, the public admission made of his transcendent merits, by the most illustrious commanders of his time. Within the last two or three years, however, a keen and bitter controversy has sprung up on the subject; and attempts have been made to dislodge Mr. Clerk from the high position to which public opinion had elevated him. The appearance of an eloquent and powerful Paper in the LIst volume of the *Edinburgh Review*,* embracing the whole scope and compass of the inquiry, has fortunately tended, in a high degree, to strengthen the entrenchments which time, and the unequivocal testimonies of the greatest minds, had raised up around him. Had Mr. Clerk been professionally connected with the Navy, so great a master of tactics, aided by all the results of a large experience, could not but have attained to its very highest honours. How often, in the history of knowledge, have great and important discoveries originated in quarters, from which they could have least been expected; and how rich and varied have been the benefits thus resulting to mankind!

Importance of tactics.

(89.) An attention to tactics cannot but be of the very first importance to a Naval commander. To neglect their cultivation is to give every advantage to the enemy, and to throw away that science which ought to be our guide. Our youngest seamen should be taught their rudiments, and a complete knowledge of them both in theory and practice should form a necessary part of Naval education. The subject is replete with the deepest interest in theory, and in its practice, is connected with the highest glory and renown. Naval tactics, it is true, have a limit in the possibilities of Navigation, and are, therefore, much less capable of variety of stratagem than the operations of armies; but, although the Naval warrior cannot place his fleet in ambush, nor at all times press the foe in his weakest part, it must not be thence inferred that there is no room left for the exercise of skill. The remark of Nelson just at the commencement of the splendid Battle of the Nile, "WHERE THERE IS SPACE FOR AN ENEMY'S SHIP TO SWING, THERE MUST BE ROOM FOR A BRITISH SHIP TO ANCHOR," proves that, in his case at least, the ready eye of genius was capable of seizing on whatever could contribute to glory and success. To devise and execute an unexpected manœuvre is, in fact, to secure the battle. This cannot be taught by books—the moment of invention is the moment of execution.

* Sir Howard Douglas has published a reply to this Article in a work entitled *Naval Evolutions*, London, 1832; but we are bound to say that it does not appear to us satisfactory.

Impressment.

(90.) On the important subject of impressment there has been much discussion during the Peace; but though the practice is so much condemned, no one has been able to suggest an adequate remedy. There can be no doubt that its employment is painful, and to be justified only by imperious circumstances. It is absolutely necessary, however, on the breaking out of a War, that the English fleet should be the first to get possession and command of the Channel; but how this can be done without the aid of impressment, has never been satisfactorily shown by those who contend for its entire abolition. It is an ancient prerogative of the Crown, on the maintenance of which mainly depends our Naval supremacy.

Stations of press-gangs.

(91.) According to Steel's *Lists*, the number of stations at which we had press-gangs during the late War varied from forty-five at the commencement, to thirty-four at the close of the War; and at these different stations there were employed from eighteen to twenty-five Captains, and from forty-seven to fifty-nine Lieutenants, with a number of men amounting on an average to not less than twenty at each station. It has been stated also, that during the late War there were never less than five line of battle ships, and sometimes eight, one 50-gun ship, three frigates, and five sloops, employed for the purpose of securing impressed men.

Small waste of life in the Naval service.

(92.) It is a circumstance most gratifying to record, that the waste of life in the trying and difficult enterprises of the past War, by no means amounted to what might have been anticipated. For example

There were on board the ships of war in all parts of the World, seamen and marines amounting,	Jan. 1, 1811, to 138,581.	whereof there died of disease, drowned, and killed in battle.	in 1810, 5183
	Jan. 1, 1812, to 136,778.		in 1811, 4265
	Jan. 1, 1813, to 138,324.		in 1812, 4211

The average of the crews being 137,894, and the average deaths, by disease, accident, and battle, 4,554, gives a rate of mortality of little more than one in $30\frac{1}{4}$;*

* Sussmilch, *Göttliche Ordnung*, vol. iii. p. 60. supposes the average measure of mortality for all Countries, taking town and villages together to be one in 36. According to Crome, the mortality in Silesia, from 1781 to 1784, was one in 30. In Guelderland, from 1776 to 1781, it was one in 27, and the same respectable authority states, that in the richest and most populous States of Europe, where the inhabitants of the towns are to the inhabitants of the country in so high a proportion as one to three, the mortality may be taken as one in 30. In several of the trades of the metropolis, the members of which, like the sailors, are between the ages of sixteen and sixty, the average mortality is greater than among seamen.

In the Naval instructions it is judiciously observed, that, "as cleanliness, dryness, and good air are essentially necessary to health, the Captain is to use his utmost endeavours to obtain these comforts for the ship's company as much as possible. The ship is always to be pumped dry; the pump-well is to be frequently swabbed, and a fire let down to dry it, (proper precautions being taken to guard against accidents;) and if the weather should prevent the lower deck ports from being opened for a considerable time, fires are to be made in the stoves, and by means of them and of wind sails the lower decks are to be kept as dry and as well ventilated as possible. The Captain is to be particularly attentive to the cleanliness of the men, who are to wash themselves frequently, and to change their linen twice every week. They are never to be suffered to sleep in wet clothes or wet beds, if it can possibly be prevented, and they

Naval Architecture.

a result of a very remarkable kind, when we consider the diversified circumstances of climate, and giving a happy close to a review of the gigantic growth of our Naval power.

Geographical position of England favourable to her Naval power.

(93.) The position of England at this moment in a Naval point of view is very remarkable. By her immense maritime superiority, she wields with ease the sceptre of the ocean. The fleets which may be preparing in the ports of those who look upon her Naval supremacy with jealousy and fear, are probably destined in future Wars to add to her own strength. Any idea of effecting a maritime coalition against her is destroyed, by her remarkable geographical position. *L'Angleterre*, says M. de Pradt,* *occupe une position centrale entre le Nord et le Midi de l'Europe; les escadres de ces deux divisions du Continent ne pourraient donc se réunir qu'à la portée des côtes de l'Angleterre et en passant sous ses canons; et ces escadres, quelles seraient-elles? Celles de la Russie? par où sortiraient-elles? A Héligoland, l'Angleterre ferme le passage du Sund; à Gibraltar, à Malte, elle intercepte tout ce qui navigue dans la Méditerranée, comme tout ce qui entre dans cette mer ou qui en sort. De Plymouth, elle bloque Cherbourg et Brest; ses côtes correspondent à celles de la Hollande, et, par ce rapprochement, la Belgique et la Hollande sont tenues en respect par la seule présence des ports Anglais: une coalition maritime contre l'Angleterre est donc matériellement impossible; moralement, elle l'est plus encore.*

Her fleets in future Wars can act in greater masses.

When France possessed Canada, Louisiana, the Antilles, and settlements in India, it might have distracted in some degree the fleets of the English; but now that the colonies of the French are so much reduced, the British fleets in future Wars will be enabled to act in greater masses than at any antecedent time. It hence becomes the policy of England, now that she has so triumphantly ascended to the very summit of maritime greatness, to consolidate her Naval power by every possible means.

Her immense Naval superiority.

Favoured by Nature in so many ways, she cannot but maintain her superiority if she be true to herself. "The vessels of a hundred different Countries wave their flags upon the Thames," says Dupin, and "nevertheless there the British flags alone surpass in number those of so many other nations. If the citizen of London is justly proud at the sight of so many fleets of merchant ships, daily arriving from the sea, or descending the river,—these, to export the products of the national industry, those, to import the produce and treasures of the most distant climes,—he cannot contemplate the busy activity that surrounds him, without feeling that he owes it all to the sovereignty of the sea. Nor are these evidences of unbounded and increasing wealth confined to the metropolis alone.

Her commerce.

He perceives Edinburgh on the shore of the most beautiful gulf of Scotland; Dublin on the spot most convenient for a rapid communication between London and Ireland; Quebec on the banks of the St. Lawrence; Calcutta on the borders of the Ganges; Halifax on the Northern coast of America; and the City of the Cape on the Southern extremity of Africa—the Cape of Storms,* which must be doubled in order to connect Europe with India;—in a word, in all parts of the World, the central points of the British power participate in the benefits of the commerce of the sea; and by these benefits contribute to the splendour, the wealth, and the power of the Country."

(94.) "In England, in Scotland, and in Ireland too, not only the Capitals just alluded to, but a multitude of cities of the first rank are built on the sea-coasts, or on the borders of large navigable rivers. Hence Liverpool, Bristol, Hull, Dundee, Aberdeen, and Glasgow, Belfast, Cork, and Waterford, become united by commerce with all the cities and all the manufactories of the interior; the interests of the maritime ports blending thus in harmony with all the great and transcendent interests of the Country. No other Country, also, is so wonderfully intersected with roads and canals; there being no point within the three Kingdoms, from which one may not, in four and twenty hours, arrive at one or other of the seas which surround them."

and Naval power mutually assist each other.

The commerce and Naval power of England hence mutually feed and protect each other. Commerce is at once the producer of wealth, and the constant, unwearied nursery of seamen; so that in the season of peace, the national enterprise is kept up, and a race of men are prepared by previous hardships, and by encountering Tropical whirlwinds and the icy seas of the Poles, to maintain the glory and renown of preceding wars.

Further steps to be made; our Dock-yards not perfect.

(95.) As the growth of our Naval power has been gradual, advancing by slow but certain steps from one condition of greatness to another, so has its administration on shore not been without obstacle and difficulty. Our Dock-yards, in no instance, present an example of an establishment that is perfect. It remains yet to be seen what a perfect Dock-yard should be; one that shall embrace magnificent basins, and be surrounded by spacious wharfs and quays; and have its most laborious duties performed by machines planned and executed by men capable of imparting to them the latest improvements in Mechanics. In former times, the various parts of the same Naval establishment were scattered; nor does the principle of concentration, so necessary for economizing time, and for uniting in a focus all the powers of a great department, seem ever to have been contemplated. Ships were built at one place, their victualling stores were received from another; their water at a third; their beer at a fourth, and their ordnance and powder

---

are often, but particularly after bad weather, to shake their clothes and bedding in the air, and to expose them to the sun and wind."

The following Table, taken from James's *Naval History* of the five great Naval victories of the last War, of the numbers killed and wounded, proves that sea-fights are not nearly so destructive as land battles. In the single Battle of Talavera there were 4714 killed and wounded, being only 145 less than the whole number killed and wounded in the Naval battles alluded to. At Talavera, also, there were only 18,500 men engaged, whereas in the five Naval fights they amounted to upwards of 61,000.

Date of the Naval victory.	Name of the Admiral who commanded the fleet.	On board the fleet.	Number of men killed.	Number of men wounded.

	Total killed and wounded..			4859

* *Appel à l'Attention de la France sur sa Marine Militaire par* M. de Pradt, *Ancien Archevêque de Malines*, Paris, 1832. *Certes*, says M. de Pradt, *les armées de l'Europe n'ont que trop su trouver le chemin de Paris; mais comment ses vaisseaux trouveraient-ils celui de Londres?*

* Cabo Tormentoso, so called by Bartholomew Diaz, a Portuguese. John I. of Portugal gave it the more inviting name of "The Cape of Good Hope."

Evils of a divided system.

from a fifth. Instead of one eye presiding over and controlling all the necessary elements for the speedy equipment of a numerous fleet, separate and sometimes conflicting interests were called into action; delays of messengers impeded the advancement of one ship, whilst currents and contrary winds, not then subdued by steam, occasioned stoppage in another. No wonder, in such a system of things, that our gallant seamen—a St. Vincent, or a Nelson,—sometimes in the ardour of their zeal, and impatient to meet the foe, bestowed words of bitter condemnation on our Dock-yards.

Those evils now under correction.

(96.) These evils, however, since the Peace, have gradually been under correction. In the two great Naval stations of Portsmouth and Plymouth, advantage has been taken of locality to bring the different departments more into union.

New Victualling establishment at Plymouth.

The Victualling Office at Plymouth, which a few years ago was placed in a narrow and inconvenient place remote from the Dock-yard, is now brought almost into juxta-position with it, forming the Eastern side of the beautiful natural basin of Hamoaze, whilst the Dock-yard and gun-wharf form the Northern. Here, in this new creation of the Rennies, is to be found every thing requisite for the victualling of a fleet. Ample storehouses, corn-mills, and bakehouses of enlarged dimensions,* slaughter-houses, cooperages, brewhouses, all under the eye of an intelligent and active superintendent,* cannot but produce, aided as it must be by the application of steam to Naval power, the most astonishing results.† Other improvements will doubtless take place in the Dock-yards themselves; machinery will be more extensively employed; railways will be laid down; Science will gain a greater ascendency; the true principles of labour will be better understood; and thus by one improvement added to another, and a rigid economy in all the departments of the State, the Naval power of England shall rise higher and higher in the scale of greatness, maintaining her transcendent superiority in spite of all the rivals who endeavour to pull her down.

Equidistant Ordinates.

Equidistant ordinates.

(97.) Ships disclose a variety of parts whose solidities and surfaces require to be computed with precision and care, but whose mixed and uncertain forms can only be reached by approximation. If we take by way of examples the surface of the water section, the figure of the immersed volume, the portions of the vessel plunged at times beneath the sea in the acts of rolling and pitching, or raised above the waves by their buoyant power, we shall find forms both of a solid and superficial kind, incapable of reduction to any regular figure.

Methods of computing irregular figures.

(98.) Various methods have been devised by Mathematicians for computing the areas and solidities of figures of this kind, by the aid of equidistant ordinates referred to a common axis. These modes of calculation are found to approximate with more or less certainty to the desired end; and much of the accuracy, whatever rule be employed, will depend on the increased number of the ordinates themselves.

Two rules commonly employed.

(99.) There are two rules commonly employed in these kinds of calculation, distinguished for their simplicity and accuracy. The first may be exhibited under the form of $(\Sigma + 4\,S + 2\,s)\,\dfrac{i}{3}$,

---

* Until within the last few years, all the flour and biscuit consumed in the Navy was furnished by private contract. The most flagrant impositions and frauds were but too generally the consequence of this mode of supply, in defiance of all the vigilance of the heads of departments. The flour and biscuit were stipulated to be of the second best quality; but instead of this, the former was generally mouldy, damaged, or of a very inferior description to that bargained for; while the latter was usually compounded of bad flour, bean meal, old worm-eaten biscuits ground down, and various other cheap or unwholesome materials. To obviate these frauds, Government, a few years ago, erected steam-mills at Deptford and Portsmouth, for the purpose of grinding flour for the Navy; and a very superior and cheaper article being the result, it was determined, in addition to grinding the flour, to attempt also the manufacture of biscuit from it, at these establishments. The impossibility of accommodating and effectually superintending the multitude of bakers required to knead the dough in the usual way, by hand, so as to effect the supplying of the whole Navy, would have rendered this praiseworthy effort, in a great measure, abortive, had not the ingenuity of Mr. Grant, storekeeper at Portsmouth, obviated the difficulty. By the attachment of a few simple pieces of machinery to the engine driving the flour-mill, the dough is now worked, rolled out, and stamped into biscuits, with an expedition inconceivable, and with a saving of two-thirds of the number of bakers required to perform these processes by hand. The flour and water are first put into a trough, through which passes an iron spindle, armed with eighteen knives, in two rows, *i. e.* nine in each row, on opposite sides of the spindle. A strap connected with the engine turns the spindle round, and by means of the revolving knives, the flour and water are in a few minutes worked into dough fit for being stamped into biscuits. The dough is now taken piecemeal from the trough, and shaped by hand into longish rolls upon two movable baking-boards, supported by small iron pillars, having castor wheels at the top: these pillars are in three rows, extending from the trough to the two rolling machines; and along the castors upon their tops the baking-boards are pushed by hand, towards the rollers, under which the dough is rolled out into thin cakes, by their backward and forward swinging motion. The baking boards are now pushed out by hand from under the rollers, and slided along three other rows of pillars, connecting the two rollers with the two cutting machines, each containing forty-two hexagonal dies, under which they are momentarily placed, and eighty-four biscuits are thus cut out by a single stamp of the two machines. The kneading, rolling, and stamping portions of the machinery being separate, can consequently be put in separate motion or at rest at the will of the baker. By the machinery at Portsmouth, under Mr. Grant's superintendence, 160,000 pounds of biscuit can be manufactured in twenty-four hours; constituting a day's ration for the crews of twenty sail of the line; and with eight or ten such pieces of machinery, biscuit rations may be daily manufactured for 160,000 men, being the greatest number of seamen and marines employed during the hottest period of the late War. The biscuit is free from flintiness, and in every respect more palatable than that made by hand, in consequence of being more thoroughly kneaded. From the rapidity of the manufacture, also, no more biscuit need now be baked than is required for immediate use, from the supply by this process being as certain as it is rapid, so that our seamen will always in future have fresh-baked and wholesome biscuit served out to them, even on foreign stations, instead of the stale, mouldy, worm-eaten, and unpalatable contract trash generally furnished during the War, which had often been baked for years before issued. It is only those who have been doomed to the penance of the contract flour and biscuit that can duly appreciate the great boon conferred on our brave seamen by this project of the Government; the above articles now supplied to the Navy being very superior in quality to those furnished for the merchant service—such, indeed, as are fitting for any gentleman's table; and all this at a much lower cost than the former contract supplies.

In addition to the usual King's mark of the broad arrow, the word "Machinery" is stamped upon the biscuits By the Naval estimates for the years 1833-34, it appears that Mr. Grant has received the sum of £2000 for his ingenious invention.

* Captain Phipps Hornby, R.N. C.B., one of the gallant heroes who commanded in the famous action off Lissa, 13th March, 1811.

† Frequently during the last War, and doubtless in all preceding Wars, ships were wind bound for a considerable time in the harbour of Hamoaze, entirely ready for sea, commanded by an ardent Captain, but unable to move. Now, the moment a ship is ready, a steamer can take her down the harbour, and, if necessary, carry her at once out to sea. Not long before this note was written, its writer saw the Caledonia, a first-rate of 120 guns, taken down by two little steamers, one lashed on her larboard bow and the other on her starboard quarter. The great ship was moving without a sail, her numerous crew were motionless, enjoying the scene. It seemed like two infants bearing a giant to some great labour.

where Σ represents the sum of the extreme coordinates, S the sum of all the *even* ordinates, s that of the *odd* ordinates, and i the common interval between the ordinates. In this rule it is essential that the uniform *laminæ*, into which the area or solidity be divided by the equidistant ordinates, should, whether those ordinates be lines or areas, be in all cases an *odd* number. This rule is founded on the supposition that each portion of the curve passing through the extremities of three successive ordinates, is a portion of a conic parabola; and hence the error arising from its general application will only be the spaces intercepted between such parabolic segments and the given curve.

(100.) Another rule was brought into practice by Atwood, wherein he supposed arcs of a cubic parabola to pass through every four successive ordinates, the number of ordinates being a multiple of 3 + 1. This rule he exhibited under the form of

$$(\mathrm{S} + 2\,\mathrm{P} + 3\,\mathrm{Q})\,\frac{3\,i}{8},$$

wherein S represents the sum of the first and last ordinates, P the sum of the 4th, 7th, 10th, &c. ordinates, Q that of the 2d, 3d, 5th, 6th, 8th, 9th, &c. ordinates, and i the common interval among them.

(101.) In the application of either of these rules to the important objects before us, care must be taken that the ordinates be sufficiently multiplied as to admit of no sudden transitions in their lengths. Should such an instance occur, and it may do so in the practice of Naval Architecture, a new abscissa should be adopted, to embrace, with the aid of new ordinates applied to *it*, the areas or solidities of such irregular parts.

The Displacement.

The displacement

(102.) It is a maxim in Hydrostatics that any floating body, whatever be its dimensions and form, will always displace a volume of the fluid in which it is immersed, exactly equivalent to the weight of the body; and the truth of the principle will be evident when we consider that the upward vertical pressure of the fluid supporting the body is exerted in precisely the same way, whether it acts on the body or on the volume of fluid previously displaced. To discover the total weight of a ship, therefore, it is only necessary to ascertain the weight of water she displaces when she floats in equilibrium; the question hence becomes one of ordinary mensuration. to find the number of cubic feet contained in the body below the plane of flotation, having its figure and necessary dimensions given.

varies between the limits of the light and load water lines.

(103.) The displacement of a ship is, however, a variable quantity contained between the limits of the light and load water lines, the first representing its minimum state, or the weight of the hull just as she is launched, and the second its maximum condition, when the vessel has received her masts and yards, her rigging, sails, ballast, water, provisions, and men, guns, powder, shot, boatswain's and carpenter's stores, &c., and in fact, all that she may require to fit her for the great purposes of war. Between these two limits, therefore, there may be every imaginable variety of displacement, and hence it is not unusual to estimate the displacement even of a single inch, both at the light and load water lines.

No invariable relation between the light and load displacements.

(104.) There seems to be no fixed and invariable relation between the light and load displacements, even in ships of the same class; and among different classes the differences are very remarkable, though here and there coincidences may be met with worthy of attention, but which, nevertheless, seem more the result of accident than of any settled design.

Displacements of several classes of ships.

(105.) In the following Table we have given the displacements of several classes of ships, derived from Mr. Edye's excellent *Naval Calculations;* and in order more clearly to show the relation of the two, we have introduced the actual light and load displacements in the first and second columns, representing the former by the constant quantity, 100, in the third column, and placing in the fourth, the proportional numbers for the corresponding displacements at the load water line.

Relations between particular ships.

(106.) Among some of these ships there exists a relation worth adverting to. The 120 and 92-gun ships, for example, are both related as 100 : 187; the 80-gun ship and the small vessel, the Rover, as well as the razée 26, and the 10-gun brig, and between one or two others there exists a close approximation. The greatest difference in the two displacements exists in the 52-gun ships, and the least in the razée of 50. The contrast between these two vessels, considering how small is the difference in their fighting forces, is very remarkable, and shows what immense powers of capacity and stowage a skilful architect may impart to his vessel, while he preserves unimpaired her fighting powers.

London	92	890
Castor	36	398
Vernon	50	559
Rover, corvette .	18	124
Snake, brig.....	16	95

Importance of the displacement.

(108.) To determine the displacement of a ship is a great and important problem. The forms of ships already constructed very frequently guide the Naval Architect in estimating the displacement of a new vessel; but cases may arise wherein he may feel disposed to have recourse to first principles, and reascending to the elements of his Art, to compute from the dimensions and specific gravities of the different materials to be employed in composing his vessel, her complement of men, her guns, the vast variety of her stores, and the absolute amount of her weight. This it will be obvious must be a laborious process, and requiring immense processes of calculation; but such obstacles will have little influence with him who is destined to extend the boundaries of the Art.

How it is applied.

(109.) Having, however, this weight, whether derived from former vessels, or by the method last adverted to, the Naval Architect will proceed to assign to it a displacement capable of giving him the stowage, the velocity, and the qualities necessary for fighting with ease and security her guns, even in a troubled sea. It would appear as if this latter element has in very many cases been singularly neglected, and that the lower deck ports have been so near the water as to afford room for great apprehension, or at least to impair the fighting powers of the ship, by the necessity that existed of frequently closing them. Among the ships now actually existing in our fleets, the height of the midship ports of a first-rate of 120 guns appears to be but 5 feet 6 inches, and of a 74, but 5 feet 8 inches above the water; whereas in the new class of the London of 92 guns the midship ports will be elevated 7 feet, and in the Vernon 9 feet. So the old corvette of 18, which had her midship ports only 4 feet 11 inches above water, in the Rover will have them 6 feet.*

* The height of the midship ports is from the circumstances of construction at a minimum elevation above the water, the fore and after ports being much higher. In the second column of the annexed Table we have the excess of the height of the fore ports above the midship ports; and in the succeeding column the height of the after ports above the same.

Importance of attending to it.

This is so important a consideration, and the mode of computing the necessary displacement corresponding to a given weight, is now so completely understood, that it would be unpardonable in the present state of our knowledge, to construct any ship without a due attention to so important a principle. It is proper to give a ship the requisite stability with as little ballast as possible, which will enable the constructor to reduce the displacement, and may facilitate the sailing and working of the vessel. Hence every weight introduced into a vessel should be kept as low as possible. In the case of a merchant-ship it is manifest that if the weight of the hull, rigging, and necessary stores be known, and the amount of displacement also, the weight of her cargo may hence be determined.

Approximation of Bouguer.

(110.) Bouguer, whose mind seems to have been directed in so many ways to simplify all the processes of computation in Naval Architecture, imagined that a close approximation to the displacement might be obtained by considering the ship's body *a semi-spheroid*, to which perhaps it assimilates more closely than to any other body. The content of a spheroid being $\frac{11}{21}$ of its circumscribing parallelopiped, he supposed the displacement might be obtained by estimating the same fractional part of the rectangular solid contained by the three principal dimensions of the ship at the water's surface. In the case of sharp ships, he modified the fraction to $\frac{11}{28}$, but it would seem that the results give considerably less than the true displacement.

More accurate methods now necessary.

(111.) The state of Naval Architecture at the present time, however, requires the application of more accurate rules. We have already alluded to formulæ, which, applied to a body like a ship, are capable of affording the solidity of the whole or any part of it immersed; and so accurate are the practical modes now adopted by the ship-builder, that the error in the total weight of a ship of 3000 or 4000 tons, is often less than half a ton. The finding the displacement of a ship is, however, only an ordinary problem in mensuration, and to a geometrician cannot present the smallest difficulty.

Sheer and body plans necessary to find the displacement.

(112.) The sheer and body plans are necessary, in order to find the displacement. Suppose A B C D, plate i. fig. 1, to represent the sheer draught of a ship, and W w the load water line for which the displacement is to be calculated. In this line take two points, E and F, each within a few feet of the stem and stern; and let the interval E F be divided into such a number of equal parts, that the number of points of division, together with the extreme points E and F, may either be represented by an odd number, or be a multiple of $3+1$. Through these points, let perpendiculars, 1, 1; 2, 2; 3, 3 .... 26, 26; 27, 27; 28, 28; be drawn to the water line, and the vessel will be divided into vertical laminæ, of equal thickness. Moreover, let O P Q, fig. 2, represent the body plan of the same ship, the lines 1, 1; 2, 2; 3, 3; 4, 4; &c. representing transverse vertical sections extending to the outside of the ship, at the several stations 1, 2, 3, 4, &c. in the sheer draught, fig. 1; those on the right hand, being the vertical sections *before* the midship section, and those on the left, the vertical sections *abaft* the same section. Moreover, below the load water line W w, let several horizontal

There are only two differences in the Table, it will be remarked, which are equal, namely, the Razée 46, and the London 92 guns.

lines, 22, 33, 44, &c. be drawn parallel to it, at some constant distance, suppose a foot from each other, both in the sheer and body plans. These sections will divide the body of the ship into horizontal laminæ of uniform thickness. Sometimes, however, the thickness of the horizontal sections in the upper body exceed those in the lower body, the form of the ship requiring the horizontal sections to be increased in the latter. If now the half breadths on the several horizontal lines of the sections in the body plan be carefully measured, by means of the scale of the drawing, the numerical results will be found as in the annexed Table. These half-breadths may also be found by means of fig. 3.

Table of Ordinates.—Vertical Sections of Middle Body. Common interval 6 feet.

Dimensions of preceding Table enable us to find the displacement both by vertical and horizontal sections.

(113.) The dimensions contained in the preceding Table will enable us to obtain the displacement, both by the vertical and horizontal sections into which the ship has been divided. If we adopt, in the first place, the vertical sections, the area of each must be found between the load water line W w, and the lowest horizontal line which has been drawn, by means of one of the formulæ before given; and to this must be added the small areas below the last-mentioned line, consisting of the remaining curvilineal areas of the section, together with the areas of the sections of the keel and false keel. These results will enable us to obtain the entire half areas of all the vertical sections from E to F. If now either of the formulæ be applied to the successive areas, the half displacement will be found between the foremost vertical section F f, and the aftermost E e. The solids *before* the section F f, and *abaft* the section E e, are then to be separately computed by applying one of the formulæ to the small horizontal areas at the extremities. These three solids added together will give the half displacement by means of the vertical sections.

Vertical sections.

Example of one vertical section.

(114.) To give an example of the mode of computing one of these vertical sections, we take the main section $\frac{16}{\phi}$. This section, in common with all the others, it has been found convenient to divide into two portions, denominated the *upper* and *lower* spaces, for the purpose of ensuring greater accuracy in the computations, the horizontal sections being estimated at the interval of one foot for the former, and 0.25 feet for the latter. We shall apply to these spaces the first formula.

UPPER SPACE.

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
1....24.9	2....25.00	3....24.65
5....20.39	4....23.08	2
45.29 = Σ	48.08	49.30 = 2 S
	4	
	192.32 = 4 S	

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4\,S + 2\,s)\ \frac{i}{3} = (45.29 + 192.32 + 49.3) \times 1$$
$$= 286.91,$$

which is the semi area of the upper portion of the main section.

LOWER SPACE.

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
1...20.39	2...19.50	3...18.54
11... 1.62	4...17.64	5...16.42
22.01 = Σ	6...14.95	7...13.24
	8... 9.90	9... 4.70
	10... 2.85	52.90
	64.84	2
	4	105.80 = 2 s
	259.36 = 4 S	

and since $\frac{i}{3} = \frac{1}{4}$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (22.01 + 259.36 + 105.8) \times \frac{1}{4} = 96.79,$$

which is the semi area of the lower portion of the main section.

Hence the entire semi area of the main section will consist of the

Semi area of the upper space	=	286.91
Semi area of the lower space....	=	96.79
Semi area to the keel	=	0.79
Semi area of the section of the keel	=	1.44
Semi area of the main section....	=	385.93

(115.) In this manner may the semi areas of all the vertical sections be obtained, the successive results of which are entered in the lowest horizontal line of the Table.

(116.) To apply these semi areas for the purpose of finding the displacement, it may be remarked, in the first place, that the ship being divided transversely into three portions, denominated the *middle body*, the *after body*, and the *fore body*, the solidity of each must be computed.

MIDDLE BODY, *or part comprised between the vertical sections* E *e*, F *f*.

The solidity of the middle body we purpose calculating by means of the formula

$$(S + 2\,P + 3\,Q)\,\frac{3\,i}{8}.$$

Extreme Areas.	Second Class of Areas.	Third Class of Areas.
1..101.72	4..224.11	2..145.51
28..151.52	7..312.49	3..186.03
253.24 = S	10..359.87	5..258.25
	13..380.89	6..288.09
	16..385.93	8..332.15
	19..375.69	9..347.48
	22..346.07	11 .368.57
	25..284.25	12..375.77
	2669.30	14..383.83
	2	15..385.49
		17..384.04
	5338.60 = 2 P	18..380.16
		20..368.18
		21..358.42
		23..330.17

		26..251.31
		27..207.11
		5660.23
		3
		16980.69 = 3 Q

and since $\frac{3\,i}{8} = 2.25$, we shall have

$$(S + 2\,P + 3\,Q)\,\frac{3\,i}{8} = (253.24 + 5338.6 + 16980.69) \times 2.25 = 50788.1925,$$

which is the half displacement of the *middle body*.

FORE BODY, *or part before the vertical section* F *f*.

We shall compute this by the same formula.

Extreme Areas.	Even Areas.	Odd Areas.
1...151.52	2...118.41	3...79.76
5... 4.96	4... 37.97	2
156.48 = Σ	156.38	159.52 = 2 s
	4	
	625.52 = 4 S	

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (156.48 + 625.52 + 159.52) \times 1 = 941.52,$$

which is the half displacement of the *fore* body.

AFTER BODY, *or part abaft the vertical section* E *e*.

This we shall compute by means of the formula

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3}.$$

Extreme Areas.	Even Areas.	Odd Areas.
1... 101.72	2...87.81	3...72.63
7... 15.71	4...57.88	5...41.94
117.43 = Σ	6...25.50	114.57
	171.19	2
	4	229.14 = 2 s
	684.76 = 4 S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (117.43 + 684.76 + 229.14) \times 0.61 = 629.113,$$

which is the half displacement of the *after* body.

(117.) Hence the whole semi displacement will consist of the

Half displacement of the middle body...	=	50788.19
Half displacement of the fore body	=	941.52
Half displacement of the after body.....	=	629.11
Half displacement of stern port and rudder	=	87.46
Half displacement of head before the rabbit........................	=	14.14
Half displacement of the ship......		52460.42

(118.) Such is the mode of computing the displacement by means of vertical sections. Let us now proceed to estimate the same by means of horizontal sections. To accomplish this, the area of each horizontal section must be found, and we select as an example that of the load water line.

(119.) This load water line* is divided, by means of the assumed points E F, into three portions, denominated the *middle space*, the *fore space*, and the *after space*. The area of each of these must be computed by means of the proper formula. Example of an horizontal section.

MIDDLE SPACE, *comprised between the points* E F.

This portion we shall compute by means of the formula

$$(S + 2\,P + 3\,Q)\,\frac{3\,i}{8}.$$

* We add in a note the absolute areas in feet of the light and

Extreme Ordinates.	Second Class of Ordinates.	Third Class of Ordinates.

	10	1488	1842	100	124
Schooner..........		1118	1447	100	129
Cutter.............		924	1200	100	130
New Class of Ships.					
London........	92	8484	9866	100	116
Castor.........	36	4840	6036	100	125
Vernon........	50	6198	7782	100	126
Rover.........	18	2187	3034	100	139
Snake.........	16	1760	2401	100	136

Here it may be remarked, that the ratios of the areas of the light and load water lines are precisely the same in the 120 and 74-gun ships, and that the new class of the London approaches extremely near to them. The Razée corvette of 26 and the new class Vernon are likewise identical in this particular. The 52-gun ship, the Castor of 36, the 18-gun corvette, and the 18-gun brig, are also precisely the same. The nearest approach to equality in these areas is in the corvette of 28 guns, and the greatest disparity exists in the new class of the Rover of 18 guns.

Fore Space, *or part before the point* F.

This portion we shall compute by means of the formula $(\Sigma + 4\,\mathrm{S} + 2\,s)\frac{i}{3}$

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
1..18.55	2..16.40	3..13.30
5..0.80	4..8.72	2
19.35 = Σ	25.12	26.60 = 2 s
	4	
	100.48 = 4 S	

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4\,\mathrm{S} + 2\,s)\,\frac{i}{3} = (19.35 + 100.48 + 26.60)$$
$$\times\, 1 = 146.43.$$

If to this there be added the area of the section of the stem and knee-head, amounting to 2.63, we shall have for the total semi area of the fore space, the quantity 149.06.

After Space, *or part abaft the point* E.

This portion we shall compute by the same formula.

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
1...16.05	2...14.69	3..12.87
7...0.80	4...10.60	5...7.51
16.85 = Σ	6...3.80	20.38
	29.09	2
	4	40.76 = 2 s
	116.36 = 4 S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4\,\mathrm{S} + 2\,s)\,\frac{i}{3} = (16.85 + 116.36 + 40.76)$$
$$\times\, 0.61 = 106.1217.$$

If to this there be added the area of the section of the post and rudder, amounting to 3.6, we shall have 109.7217 for the total semi area of the fore space.

(120.) Hence the entire semi area of the load water line will consist

The semi area of the middle space. ..	=	3856.3875
semi area of the fore space	=	149.06
semi area of the after space....	=	109.7217
semi area of the load water line.	=	4115.1692

(121.) In the same way may the semi areas of all the other horizontal sections be obtained, the successive results being entered in the last vertical column of the Table.

To apply these areas to the displacement, it is to be remarked, that the body of the vessel is supposed to be divided into two portions, denominated respectively the *upper body* and the *lower body*, each of which we shall proceed to compute.

Upper Body.

Extreme Areas.	Even Areas.	Odd Areas.
1.4115.17	2..3884.75	5..3510.34
5..2450.67	4..3028.73	2
6565.84 = Σ	6913.48	7020.68
	4	
	27653.92 = 4 S	

Naval Architecture.

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (6565.84 + 27653.92 + 7020.68) \times 1 = 41240.44$$

for the semi displacement of the upper body.

In like manner we proceed to the computation of the

Lower Body.

Extreme Areas.	Even Areas.	Odd Areas.
1..2450.67	2..2290.92	3..2128.97
2 . 235.65	4..1977.61	5..1783.96
2686.32 = Σ	6..1591.72	7..1356.64
	8..1033.54	9.. 615.79
	10.. 392.99	5885.36
	7286.78	2
	4	11770.72 = 4 s
	29147.12 = 4 S	

and since $\frac{i}{3} = 0.25$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (2686.32 + 29147.12 + 11770.72) \times 0.25 = 10901.04 \text{ cubic feet}$$

for the semi displacement of the lower body.

(122.) Hence the whole semi displacement by horizontal sections will be

Semi displacement of upper body....	=	41240.44
Semi displacement of lower body....	=	10901.04
* Semi displacement of solid below lower body....................	=	107.13
Semi displacement of keel and rudder, &c.	=	217.18
Semi displacement by horizontal sections........................	=	52465.79

A mean of the vertical and horizontal sections should be taken.

(123.) To ensure accuracy, a mean of the displacements calculated by the vertical and horizontal sections should be taken, amounting in the present instance to 52463.1. Hence the whole displacement will be 104926.2; or dividing by 35 the number of cubic feet of sea-water in a ton, the absolute displacement in tons will be 2998.89 tons.

Table to show in what way the displacement is made up.

(124.) To show in what way the displacement is made up by the different weights, constituting the hull and stores, &c. of each vessel, we have drawn from Mr. Edye's *Naval Calculations* the following important particulars.

Weight of the various Articles composed in the Hull of each Ship and Vessel.†

Number of guns	120	80	74	Razée. 50	52	46	Razee Corvette. 26	28	Corvette. 18	Brig. 18	Brig. 10	Schooner.	Cutter.

* It is but rarely that the load water line is parallel to the keel, and the same may be said of the light water line. In the different classes of ships which follow, the excess of the after load draught above the forward load draught is given in the second column, and similar differences of the light water draught are recorded in the last.

Class of Ships.	Excess of after load draught above forward load draught. Ft.	In.	Excess of after load draught above forward light draught. Ft.	In.
120	1	5	2	4
80	3	3	4	7
74	2	10	4	1
52	1	0	2	10
46	1	8	4	9
28	0	5	2	2
Corvette..18	0	7	1	10
Brig 18	3	3	4	10
Brig 10	1	1	2	5
Schooner..10	2	6	2	11
Cutter	6	10	6	6

In every instance, excepting the cutter, the difference of the after and forward light water draughts exceeds the difference of the corresponding load water draughts. In calculating the load or light displacements, it is manifest in carrying down the successive horizontal planes, that a portion of the vessel must remain, requiring a separate computation, in all cases where the two draughts of water are not precisely the same.

Actual weights of certain important elements.

† We throw into a note some numerical results connected with the weight of weights contained in the preceding Table, on account of their great importance to the ship-builder. Such results illustrate in a high degree the statistics of ship-building, and are also of great value in

Weight of the Masts and Yards, and of the Spare Gear, Rigging, and Blocks, of the Sails, Cables, and Anchors, Water, Provisions, and Men; of the Powder; Gunner's, Boatswain's, and Carpenter's Stores; of the Guns and Shot, and weight of the Boats when fitted for Foreign Service.

Weight of a cubic foot of timber green and seasoned.

(126.) In the following Table will be found the weight of a cubic foot of timber in a green and seasoned state, at present used in ships and vessels of war, derived also from Mr. Edye's *Naval Calculations.* This Table will assist the ship-builder in determining the weight of the timber materials necessary in computing a ship's displacement.

Names of Timber.		Green. lbs.	oz.	Seasoned. lbs.	oz.
English oak		71	10	43	8
Dantzic oak		49	14	36	0
African teak		63	12	60	10
Indian teak, green or seasoned, about the same	Malabar	...		52	15
	Rangoon	...		26	4
Indian mast peon		48	3	36	0
Cedar		32	0	28	4
Larch		45	0	34	4
Riga fir		48	12	35	8
New England fir		44	12	30	11
Elm		66	8	37	5
Beech		60	0	53	6
Ash		58	3	50	0

The Malabar teak is the heaviest, and the Rangoon the lightest of all Indian teaks used in ship-building.

The average weight of the timber materials in a ship or vessel of war is about 50 pounds to the cubic foot; and for the masts and yards about forty pounds.

Displacement of an inch at light and load water lines.

(127.) It is often necessary to know the amount of the displacement for a single inch in depth, both at the light and load water lines. In like manner, it is useful to know the displacement of one foot of the midship section at the same lines. The results for the different classes of ships in tons are inserted in the next Table, from Mr. Edye's *Naval Calculations.*

Class of Ship.	Guns.	Displacement of one inch at the light line. Tons	Cwt.	Displacement of one inch at the load line. Tons	Cwt.	Displacement of one foot of the midship section at the light line. Tons	Cwt.	Displacement of one foot of the midship section at the load line. Tons	Cwt.

Displacement augmented by motion of the ship and tide.

(128.) It may also be useful to advert to one or two circumstances more which influence the amount of displacement. In what we have before said, the consideration has been limited to the conditions of a ship at rest in still water; but it has been observed, that when the ship and the water are relatively in motion, either by the ship being at rest, and the water in motion, or by the ships moving and the waters being at rest; or again by the ship and water moving with unequal velocities or in different directions, the depth to which the ship sinks must be determined in connection with other considerations. When a vessel is at anchor also in a strong tideway, or at sea under a press of sail, she must sink several inches deeper than when at anchor in still water. Romme observed a frigate which was lashed to a sheer hulk in the river Charente sink two inches deeper when the velocity of the stream was great, than when its motion was only just sensible.

How accounted for.

(129.) This may be accounted for on the principle, that when a particle of water is impressed with motion, and passes along the surface of a body, it no longer exerts a pressure equally in all directions, as in the case of water in a state of rest, but has a greater tendency to escape in the direction of its motion than any other, and hence causes a less vertical pressure on the surface of the body than when at rest. The total pressure of the particles of water in contact with the body being less than before, and having been, when at rest, exactly equivalent to sustain the body, that body must of necessity sink deeper, until a balance is obtained between the vertical pressure and the weight. The pressure of a particle of water in motion is proportional to its depth below the surface of the water, minus the depth due to the velocity estimated in the direction of its motion. Bernoulli, the Abbé Bossut, and Romme proved these principles by experiment.*

* The following simple and decisive experiment was made by Romme. He had two tubes, one of them straight, as *a b*, and the other curved, as *c d e*, fig. 4, but both having open ends, and capable of receiving a float, *g f*, the lower part of which was cork, and the upper a graduated rod. These tubes with their floats were first plunged into still water, and the divisions corresponding with the upper orifices of the tubes observed. The tubes were then placed in running water, the current being in the direction *h i*, and the bent tube *c d e*, with its lower end turned in the same direction. The floats in both tubes were then observed to have sunk an inch below their position in still water. The bent tube was in the next place turned so as to present its orifice to the current, when the float rose an inch above the position it had in still water. The same tube was then placed with the lower end perpendicularly to the direction of the current, when the float sunk an inch below its position in still water. Romme measured the velocity of the current, and found the water ran 70 feet in 30″, or that its velocity was that due to an inch and a line nearly, corresponding with the distance the floats in the tubes were elevated or depressed in the experiments. Other experiments in currents of different velocities produced similar results. In some instances the depression and elevation of the floats were as much as five or six inches, being always the height due to the velocity of the current. He ascertained also that the results were the same, to whatever depth the tubes were plunged into the water.

Difference of immersion of ships in fresh and salt water.

(130.) It is but seldom a ship of war floats in fresh water, though a merchantman may often do so. We, however, insert in the next Table the difference in the immersions of several ships in fresh and sea water, and from which it appears, that a ship of 120 guns sinks nearly six inches deeper in the former than in the latter. The difference also produced in the two load lines from the two specific gravities is worthy of attention. In the ship just adverted to, it amounts to 143 tons 8 cwt. In the last column we have given the quantity necessary to raise or immerse the ship an inch at the load or sea line. This useful Table is due also to Mr. Edye.

Rate of Ship, or her Number of Guns.	The Ship deeper in River Water than in Sea Water.	Difference in the two Load Lines from the Specific Gravity of Fresh and Salt Water.		Quantity to raise or immerse the Ship an Inch at the Load or Sea Line.	
No.	Inches.	Tons.	Cwt.	Tons.	Cwt.
120	$5\frac{7}{8}$	Equal to 143	8	24	0
74	$5\frac{1}{4}$	93	14	17	17
46	$3\frac{5}{8}$	45	6	12	5
28	$3\frac{1}{4}$	24	6	7	9
18	$2\frac{1}{2}$	14	6	5	13
10	$2\frac{1}{8}$	9	6	4	7
Cutter.	$1\frac{3}{4}$	5	2	2	17

Displacement deduced from different specific gravities of water.

(131.) The displacement may be deduced from the different specific gravities of the water in which a vessel floats. For suppose s and s' to be the specific gravities of fresh and salt water, and D and D′ the corresponding displacements; then by a well-known principle in Hydrostatics

$$D\,s = D'\,s',$$

and $$s : s' :: D' : D.$$

Hence $$s' - s : s' :: D - D' : D.$$

Now, since it requires the application of a given weight to change the displacement D′ into D, it is manifest the actual displacement may be found by knowing this weight, and the values of s and s'. Thus suppose it required an additional weight of 25 tons to bring a vessel down, when floating in salt water, to the load line she possessed when swimming in fresh water, a cubic foot of the former weighing 1026 ounces, and of the latter 1000, we shall have

$$\overset{\text{oz.}}{26} : \overset{\text{oz.}}{1000} :: \overset{\text{tons.}}{25} : \overset{\text{tons.}}{961.54}$$

for the actual amount of the displacement sought.

On the Centre of Gravity of the Displacement.

(132.) In attempting to find the centre of gravity of the displacement, a point involving so many important considerations with regard to the stability, it is manifest when the vessel is floating in equilibrium, that it must be somewhere found in the vertical longitudinal section which passes through the middle of the sternpost and stem; and that the question becomes therefore reduced to the finding its position with regard to two coordinate planes, one of which has reference to the position of the point with regard to the length of the vessel, and denoted by E e in the figure, and the other with regard to its depth below the other coordinate plane W w.

How it may be found.

(133.) We have already explained in our Treatise on Mechanics, a mode by which this may be accomplished with respect to both of the planes just mentioned, by what is termed the theory of moments; and it is obvious that with regard to the position of the centre of gravity of the displacement longitudinally, we shall have three separate computations to make, two relating to the middle and fore bodies of the vessel, and to be esteemed *positive*, and a third as respects the after body, to be regarded as *negative*. The general Table of ordinates will furnish us with the necessary elements for this purpose.

(134.) To estimate the moment of the middle body, we must, in the first place, obtain the resulting products recorded in the last column of the next Table.

Number of the Transverse Vertical Sections.	Half Areas of the Vertical Sections comprised between the Sections 1 and 28.	Distances of the Vertical Sections from the Primitive Section E e.	Resulting Products.
1	101.72	0	0.0

		474762.06
		3
		1424286.18 = 3Q

Naval Architecture.

and since $\frac{3i}{8} = 2.25$, we shall have

$$(S + 2P + 3Q)\frac{3i}{8} = (24546.24 + 443971.44 + 1424286.18) \times 2.25 = 4258808.685$$

for the moment of the half middle body.

(135.) To compute, in the next place, the moment of the fore body, it is to be observed that the distances of the successive vertical sections in it must still be estimated from the primitive plane E *e*, and therefore gives for the interval between the section passing through the point 2 in the fore body, and that plane, 165 feet. Hence we shall obtain the following resulting products.

Number of the Transverse Vertical Sections.	Half Areas of the Vertical Sections comprised between the Sections F *f* and 5.	Distances of the Vertical Sections from the Primitive Section E *e*.	Resulting Products.
28.1	151.52	162	24546.24
2	118.41	165	19537.65
3	79.76	168	13399.68
4	37.97	171	6492.87
5	4.96	174	863.04

To apply these resulting products to the formula

$$(\Sigma + 4S + 2s)\frac{i}{3},$$

we shall have

Extreme Products.	Even Products.	Odd Products.
1..24546.24	2..19537.65	3..13399.68
5.. 863.04	4.. 6492.87	2
25409.28 = Σ	26030.52	26799.36 = 2*s*
	4	
	104122.08 = 4S	

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4S + 2s)\frac{i}{3} = (25409.28 + 104122.08 + 26799.36) \times 1 = 156330.72$$

for the moment of the half fore body, exclusive of the knee of the head amounting to 2474.64. Hence the entire moment of the half fore body will amount to 158805.36.

(136.) To estimate the moment of the after body, the distances of the vertical sections in it must in like manner be estimated from the same primitive vertical section E *e*. This will give the resulting products in the last column of the next Table.

Number of Transverse Vertical Sections.	Half Areas of the Vertical Sections comprised between E *e* and 7.	Distances of the Vertical Sections from the Primitive Section E *e*.	Resulting Products.
1	101.72	0.0	0.0
2	87.81	1.83	160.69
3	72.63	3.66	265.83
4	57.88	5.49	317.76
5	41.94	7.32	307.00
6	15.66	9.15	143.29
7	15.71	10.98	172.50

To apply these resulting products to the formula

$$(\Sigma + 4S + 2s)\frac{i}{3},$$

we shall have

Extreme Products.	Even Products.	Odd Products.
1... 0.0	2...160.69	3...265.83
7...172.5	4...317.76	5...307.00
172.5 = Σ	6...143.29	572.83
	621.74	2
	4	1145.66 = 2*s*
	2486.96 = 4S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4S + 2s)\frac{i}{3} = (172.5 + 2486.96 + 1145.66) \times 0.61 = 2321.1232,$$

which is the moment of half the after body exclusive of the post and rudder. And since the moment of the post and rudder amounts to 1141.35, we shall have for the entire moment of the semi after body, the quantity 3462.4732.

(137.) Now since by the conditions of the primitive plane E *e*, the moments of the middle and fore body are regarded as positive, and that of the after body is negative, we shall have for the absolute amount of the moments,

Moment of the half middle body. .	=	+ 4258808.685
Moment of the half fore body. . . .	=	+ 158805.36
		+ 4417614.045
Moment of the semi after body . .	=	− 3462.4732
Absolute amount of the moments .	=	+ 4414151.5718

(138.) And since by well-known considerations, the position of the centre of gravity with regard to the primitive vertical plane may be found by the formula $\frac{M}{D}$, where M represents the sum of the moments, and D denotes the corresponding displacement, and that we have already found D = 52460.42, we shall hence have

$$\frac{M}{D} = \frac{4414151.5718}{52460.42} = 84.14,$$

which is the distance of the centre of gravity of the displacement before the primitive section E *e*. And since the distance from this same section to the middle point of the load water section is 81.50 feet, it is manifest that the centre of gravity of the displacement is before the middle of the length of the load water section, when measured from the after part of the rabbet of the sternpost to the fore part of the rabbet of the stem, 2.64 feet.

Position of the centre of gravity of displacement with regard to the length,

(139.) To proceed in the next place to the computation of the depth of the centre of gravity of the displacement below the plane of the load water section, we must compute separately the moments of the upper and lower bodies. The preparatory products for the former of these are given in the next Table.

and with regard to the depth.

Number of the Water Sections.	Half Areas of the Water Sections.	Distances of the Water Sections from the Load Water Section.	Resulting Products.
1	4115.17	0	0.0
2	3884.75	3	11654.25

	107656.88	88969.27
	4	2
	430627.52 = 4 S	177938.54 = 2*s*

and since $\frac{i}{3} = 0.25$, we shall have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (34003.21 + 430627.52 + 177938.54) \times 0.25 = 160642.3175,$$

which is the moment of half the lower body,

(141.) Hence the sum of all the moments of the immersed body will be:

Moment of half the upper body...	= + 227183.40
Moment of half the lower body...	= + 160642.3175
Moment of half the solid below the lower body............	= + 2121.17
Moment of half keel, rudder, &c...	= + 6767.90
Total sum of all the moments..	= + 396714.7875

And since as before the function $\frac{M}{D}$ represents the distance of the centre of gravity of the displacement below the assumed plane of the water section, we shall have

Its position.

$$\frac{M}{D} = \frac{396714.7875}{52460.42} = 7.56 \text{ feet}$$

for that distance.

(142.) It forms a useful subject for investigation in many important points connected with ship-building, to be enabled to compare the centre of gravity of the load water section so often referred to, with the centre of gravity of the displacement, reckoned in the same horizontal direction; and also the centre of gravity of the midship section, with the corresponding position of the same point of the immersed volume. The same process must be employed for obtaining the centre of gravity of the surface as for the solid; and in the same manner as for the solid, the moments of the load water line must be separated into the middle space, the fore space, and the after space, and each have its proper sign of *plus* or *minus* prefixed to it, according as it is situated with regard to the primitive section passing through the point E.

Useful to compare centre of gravity of load water section with centre of gravity of displacement.

3	13.30	168	2234.40
4	8.72	171	1491.12
5	0.80	174	139.20

Applying these resulting products to the formula

$(\Sigma + 4S + 2s)\frac{i}{3}$, we shall have

Extreme Products.	Even Products.	Odd Products.
1..3005.10	2..2706.00	3..2234.10
5.. 139.20	4..1491.12	2
3144.30 = Σ	4197.12	4468.20 = 2s
	4	
	16788.48 = 4S	

and since $\frac{i}{3} = 1$, we shall obtain

$$(\Sigma + 4S + 2s)\,\frac{i}{3} = (3144.30 + 16788.48 + 4468.20) \times 1 = 24400.98$$

for the moment of the fore space. Adding to this the moment of the stem section amounting to 462.93, we shall have for the whole moment of the fore space the quantity 24863.91.

(144.) In the same way we must proceed for the moments of the after space.

Number of the Ordinates.	Ordinates of the Load Water Section in the after Space.	Distances of the Ordinates from the Primitive Ordinate E	Resulting Products.
1	16.05	0.0	0.0
2	14.69	1.83	26.88
3	12.87	3.66	47.10
4	10.60	5.49	58.19
5	7.51	7.32	54.97
6	3.80	9.15	34.77
7	0.80	10.98	8.78

Applying these resulting products to the formula

$$(\Sigma + 4S + 2s)\,\frac{i}{3},$$

we shall have

Extreme Products.	Even Products.	Odd Products.
1....0.00	2....26.88	3....47.10
7....8.78	4....58.19	5....54.97
8.78=Σ	6....34.77	102.07
	119.84	2
	4	204.14 = 2s
	479.36 = 4S	

and since $\frac{i}{3} = 0.61$, we shall obtain

$$(\Sigma + 4S + 2s)\,\frac{i}{3} = 422.29$$

for the moment of the after space, exclusive of the post and rudder, amounting to 47.70. Hence the entire moment of the after body will be 469.99.

(145.) The moments of the middle and fore space being regarded as *positive*, that of the after space must be esteemed *negative*. Hence we shall have

Moment of middle space..........	=	+ 315192.465
Moment of fore space............	=	+ 24863.910
		+ 340056.375
Moment of after space	=	− 469.990
Absolute amount of the moments of the water section.............		+ 339586.385

(146.) Now, by the last column of the general Table of ordinates it appears, that the semi horizontal area of the water section amounts to 4115.17; and hence the function

$$\frac{M}{D} = \frac{339586.385}{4115.17} = 82.52 \text{ feet.}$$

Position of centre of gravity of load water section.

(147.) The centre of gravity of the load water section is thus found to be 82.52 feet from the ordinate 1; and since the distance of the middle point from the same ordinate is 81.50, the distance of the centre of gravity of the load water line before the middle is 1.02 feet.

(148.) Thus it appears, that the centre of gravity of the load water section is not so far before the middle as

Naval Architecture.

the centre of gravity of the displacement itself, which is a principle to be observed in the construction of ships.

Positions of centre of gravity of displacement in several classes of ships.

(149.) We throw into the next Table the positions of the centre of gravity of displacement in the several classes of ships: first, with regard to the centre of the plane of flotation; secondly, as to its position *above* the lower side of the keel; and thirdly, as regards its depth *below* the load water line. These important elements have been drawn from Mr. Edye's admirable Tables.

Class of Ship.		Distance of the Centre of Gravity of Displacement before the Centre of Flotation.		Distance of the Centre of Gravity of Displacement above the lower side of the Keel.		Distance of the Centre of Gravity of Displacement below the Load Water Line.

The nearest approach of the centre of gravity of displacement to the centre of flotation is in the cutter, and the next to it is the 18-gun-brig. The two points are at the greatest distance in the Vernon.

On the Centres of Gravity of the Solids of Immersion and Emersion.

Centres of gravity of solids of immersion and emersion.

(150.) It is not only of importance that the true amount of the solids of immersion and emersion should be calculated, but the positions of their centres of gravity also, in order to discover if they are found in the same transverse section, or at the same common distance before the aftermost section. Supposing the result of the computation should prove this not to be the case, such alterations must be made in the body as the results seem to require.

(151.) To determine in the first place the distance forward of the IMMERSIONS CENTRE OF GRAVITY, we must remember there are three systems of moments to compute; *viz.* those in the MIDDLE BODY, the FORE BODY, and the AFTER BODY.

Naval Architecture.

	8044.48	2
	4	11109.04 = 2 *s*
	32177.92 = 4 S	

and since $\frac{i}{3} = \frac{2}{3}$, the sections here being now supposed to be two feet apart, we shall have

$$(\Sigma + 4\,\text{S} + 2\,s)\,\frac{i}{3} = (5058.00 + 32177.92 + 11109.04) \times \frac{2}{3} = 32229.97,$$

which is the amount of the moment in the fore body.

MOMENTS IN THE AFTER BODY.

Extreme Products.	Even Products.	Odd Products.
1. . . . 0.00	2. . . . 39.93	3. . . . 67.05
7. . . . 0.44	4. . . . 69.77	5. . . . 41.43
0.44 = Σ	6. . . . 14.18	108.48
	123.88	2
	4	216.96 = 2 *s*
	495.52 = 4 S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4S + 2s)\frac{i}{3} = (0.44 + 495.52 + 216.96) \times 0.61 = 434.8812,$$

which is the value of the moment in the after body.

(152.) Now, since the moments in the middle and fore body are to be regarded as *positive*, and that in the after body as *negative*, we shall have

Moments in the middle body	=	+ 622325.025
Moments in the fore body	=	+ 32229.970
		+ 654554.995
Moment in the after body	=	− 434.8812
Hence whole moment of the immersion	=	+ 654120.1138

And since the solid content of the immersion has been found to be 7860.9703, we shall have

Position of centre of gravity of immersed volume before section 1.

$$\frac{M}{D} = \frac{654120.1138}{7860.9703} = 83.21 \text{ feet},$$

which is the distance of the centre of gravity of the immersed volume before section 1 of the middle body.

(153.) A similar mode of proceeding must be pursued for finding the distance forward of the Emersions Centre of Gravity.

$$(\Sigma + 4S + 2s)\frac{i}{3} = (3968.95 + 23370.08 + 8049.88) \times \frac{2}{3} = 23592.61,$$

which is the amount of the moment in the fore body.

Moments in the After Body.

Extreme Products.	Even Products.	Odd Products.
1...0.00	2...25.71	3 ..32.27
7...2.18	4...39.88	5...26.20
2.18 = Σ	6...11.25	58.47
	76.84	2
	4	116.94 = 2s
	307.36 = 4S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4S + 2s)\frac{i}{3} = (2.18 + 307.36 + 116.94) \times 0.61 = 260.1528,$$

which is the value of the moment in the after body.

(154.) Two of these moments being positive, and the remaining one negative, we shall have

Moments in the middle body.	=	+ 626645.16
Moments in the fore body	=	+ 23592.61
		+ 650237.77
Moments in the after body.	=	− 260.1528
Hence whole moment of the emersion	=	+ 649977.6172

And since the solid content of the emerged volume = 7815.3119, we shall obtain

$$\frac{M}{D} = \frac{649977.6172}{7815.3119} = 83.17 \text{ feet},$$

which is the distance of the centre of gravity of the emerged volume before section 1 of the middle body.

Position of centre of gravity of emersion before section 1.

(155.) Since then the centres of gravity of the solids of immersion and emersion are found so very nearly in the same plane, differing only $\frac{4}{100}$ths of a foot, the construction, so far as regards this very important particular, may be esteemed correct.

(156.) Hence it follows, that the centre of gravity of the displacement is 0.95 feet before the mean distance of the centres of gravity of immersion and emersion; and the latter point 0.67 feet before the centre of gravity of the load water section.

If these centres be not found in some vertical plane, the ship will revolve round different axes.

(157.) Unless these centres of gravity be found as nearly as possible in the same transverse vertical plane, a ship is liable to revolve round different horizontal axes, producing irregular motions and impulses,—circumstances by no means to be desired. Nor should this property belong to one inclination only, but for every angle through which a vessel revolves. In the case

Naval Architecture.

of the Bulwark of 76 guns, the centre of gravity of her immersion at an angle of ten degrees' inclination, was only six inches in a fore and aft direction from the centre of gravity of the emersion, her character for regular and easy motion being of the best kind. In some other cases, however, where ships have been remarked for their uneasy motion, as to this diagonal pitching, these centres have been removed from the same plane three or four feet. According to Mr. Morgan this very important principle was first attended to in the construction of English ships.

Stability.

Stability.

(158.) The question of stability is divided naturally into two branches, named Hydrostatic stability, or the stability of a floating body at rest, and Hydrodynamic stability, or the stability of a floating body in motion.

Necessity of investigating it in a very general point of view.

(159.) The Naval architect should investigate the subject in the most general point of view, and by making himself acquainted with the singular relations which its application to bodies of different forms disclose, be enabled to investigate with confidence the stability of a ship of any kind, whether destined for commerce or the purposes of war.

Relation between immersed and whole floating body.

(160.) A slight acquaintance with Hydrostatics will convince us that a relation exists between the part of a floating body immersed in the sea, and the whole amount of its magnitude, dependent on the relative specific gravities of the fluid and solid mass. A body may, indeed, be immersed in a fluid in many different ways so as to preserve this relation entire, but there may not be one position in which it will permanently rest; nor can a state of quiescence be at any time obtained, until the vertical lines which pass respectively through the centres of gravity of the whole body and its immersed volume completely coincide.

Three kinds of equilibrium: Stability, Instability,

(161.) A floating body assumes three kinds of equilibrium when these centres of gravity are in the same vertical line: 1st, *the equilibrium of stability*, or that in which the solid permanently floats in a given position.

2dly, *the equilibrium of instability*, or that in which the body spontaneously oversets, unless sustained by some external force; and which kind of equilibrium takes place, when a needle or any other sharp pointed body is attempted to be raised on a smooth horizontal plane.

Indifference.

And 3dly, *the equilibrium of indifference*, occupying a kind of limit between the other two, when the solid rests on the fluid indifferent to motion, having no tendency to right itself when inclined, or in any way to increase its inclination.

The first most concerns the ship-builder.

(162.) The first of these conditions is that which most concerns the ship-builder thoroughly to understand. Among the great variety of bodies which permanently float on the surface of a fluid, experience tells us there are some more easily inclined from a quiescent position than others. Many bodies, after undergoing an inclination, return to their original positions with greater readiness and power than others; and this is particularly observable among ships at sea, where the same impulse of the wind produces a much greater inclination from a vertical position in one vessel than in another. Hence it is, that in order to form a due estimate of the resistance to inclination, and to be able to compute the absolute stability for different angles of inclination, Mathematicians have been induced to investigate rules, by which the stability of ships may be computed prior to their construction, when their dimensions and weight are known.

Naval Architecture.

Different ways in which the subject of stability has been computed. Investigations of Atwood.

(163.) There have been many beautiful essays published on the stability of floating bodies, some treating it theoretically and adorning the subject with the richest flowers of analysis, whilst others have aimed at a more practical character. The name of Atwood is rendered immortal in the annals of ship-building by two admirable Treatises on the stability of floating bodies, published in the *Philosophical Transactions* for 1796 and 1798. In these Papers he demonstrated, that a more accurate attention to the forms and dimensions of the solids immersed and emerged in consequence of the inclination was absolutely necessary; and leaving the consideration of infinitely small angles of inclination, which in so many cases leads to erroneous or inconclusive results, created a formula for finite angles of inclination, and which required as a fundamental condition, a rigid attention to the form of the body. Before entering on the consideration of this formula, we shall, however, briefly advert to a few remarkable particulars deduced by Mr. Atwood, respecting the equilibrium of floating bodies.

Positions of equilibrium deduced by Atwood.

(164.) In the first place, the total number of positions of equilibrium of a floating body, movable round a fixed axis, is in all cases an *even number;* and secondly, that the number of positions of equilibrium of stability, is equal to the number of positions of equilibrium of instability; so that in turning round an invariable axis, the body must alternately pass from a position of stability to one of instability. There must in every body be at least one position of equilibrium of absolute stability, and one of absolute instability.

Investigation of a square parallelopiped.

Numerical limits connected with its floating.

(165.) There are some relations depending, moreover, on the form and specific gravity of the body, which it is proper to advert to more particularly. If we take, by way of example, a square parallelopiped, floating freely on a fluid's surface, it will be found that so long as the specific gravity of the body is confined between the limits of zero and 0.211, the solid will permanently float on the fluid with a flat surface upward, parallel to the horizon. That when the specific gravity rises to any magnitude between the limits 0.211 and 0.25, the parallelopiped will float permanently with a flat surface upward, but inclined to the horizon at different angles, whose limits are zero, corresponding to the specific gravity 0.211, and 26° 34′ corresponding to the specific gravity 0.25. If, again, the specific gravity be found between the limits $0.25 = \frac{8}{32}$ and $\frac{9}{32}$, the parallelopiped will float with one angle only immersed beneath the surface, its diagonal being inclined to the vertical at various angles, depending on the specific gravity, the limits being 18° 26′, corresponding to the specific gravity $\frac{8}{32}$, and zero corresponding to the specific gravity $\frac{9}{32}$. As soon, however, as the specific gravity is increased beyond $\frac{9}{32}$, the solid will permanently float with one of its diagonals vertical, until the specific gravity reaches the limit of $\frac{23}{32}$. If again the specific gravity be augmented to any quantity between $\frac{23}{32}$ and $\frac{24}{32}$, the floating body will repose with its diagonal variously inclined, the limits being zero, corresponding to the spe-

cific gravity $\frac{23}{32}$, and 18° 26′ corresponding to the specific gravity $\frac{24}{32}$, three angles of the solid being in this case immersed beneath the fluid's surface. If, moreover, the specific gravity be augmented to a quantity between the limits $\frac{24}{32}$ and 0.789, the solid will float with a flat surface upward, inclined to the horizon at sundry angles depending on the specific gravity, the limiting angles being 26° 34′, corresponding to the first specific gravity $\frac{24}{32}$, or 0.75, and zero corresponding to the other specific gravity 0.789. Finally, when the specific gravity reaches a magnitude between the limits of 0.789 and unity, the assumed specific gravity of the fluid, the solid will float permanently with a flat surface parallel to the horizon.

(166.) Hence we infer, that while the square parallelopiped floating on the fluid's surface, has revolved completely round its longer axis, or through 360°, it has passed through either sixteen or eighteen positions of equilibrium. When the specific gravity is found between the limits 0.211 and 0.281, or between 0.719 and 0.789, the number of those positions will be sixteen, eight of which are positions of permanent, and the remaining eight of unstable equilibrium; the two kinds of equilibrium succeeding each other alternately, as the solid revolves. In case the specific gravity should be of any value not included within these limits, the solid in completing its rotation will pass through eight positions only of equilibrium, four of which are of permanent and four of unstable equilibrium.

Important for the young Naval architect to pursue this subject.

(167.) A number of singular properties might be given depending on the forms of bodies and their different specific gravities, and which it would be useful for the young Naval architect to investigate; but our limits will only permit us to refer to one or two. In the case of a cylinder placed on a fluid with its axis vertical, if the diameter of the base has to the axis a greater ratio than $\sqrt{2}:1$, no value can be given to the solid's specific gravity, which will cause it to float in a state of insensible equilibrium; or in other words, there is no specific gravity separating the cases in which the cylinder will float permanently, from those in which it will overset when the axis is placed vertically. The cylinder under these circumstances must always float permanently with its axis vertical. When, however, the diameter of the base has to the length of the cylinder, a less ratio than $\sqrt{2}:1$, two values of the specific gravity may be found, which form limits to the cases in which the solid floats with stability or oversets. If the specific gravity be given, the relation of the cylinder's length to the diameter of the base may be fixed which limits the cases of stability or instability of floating with the axis vertical. If, for example, the specific gravity be 0.75, and the diameter of the base has a greater ratio to the axis than $\sqrt{\frac{3}{2}}:1$, the cylinder will float permanently with its axis vertical; but if the ratio be less, the cylinder will overset.

Some instances.

(168.) If we take the case of a parabolic conoid,—a body connected with the immortal name of Archimedes, we shall find in the first place that when the axis is to the parameter in a less ratio than 3 : 4, no specific gravity can be found which will make the solid float in the equilibrium which is a limit between the stability and instability of floating. Secondly, that if the specific gravity of the solid bears a g to that of the fluid, than that which the s the difference between the axis and three-fourths parameter has to the square of the axis, when tha is placed vertically, the solid will float with stability that position. Thirdly, that if the specific gravity of th solid has a less ratio to the specific gravity of the fluid than that which the square of the above difference has to the square of the axis, the solid will overset when placed on the fluid with its axis vertical, and will settle permanently with its axis inclined to the vertical line. If the specific gravity of a parabolic conoid be less than the limit just referred to, and the axis be to the parameter in a greater ratio than 6 to 8 and less than 15 to 8, it will float permanently on the fluid with its axis inclined to the horizon, and with its base wholly visible above the surface. These beautiful properties we owe to that admirable analysis, which, in the hands of Archimedes, was cultivated with such transcendent success. Too much neglected by the moderns, it is refreshing to turn occasionally to these splendid remains of ancient genius. The investigations of Archimedes are contained in the second book of his tract, *De iis quæ in humido vehuntur.*

Tabular results of the properties of different bodies.

(169.) In order to place before the young ship-builder a few connected results on this interesting and important subject, we throw into the next Table Mr. Atwood's comparative stabilities of several bodies. Some elements, it will be perceived, are adopted by him as common, such as the breadth of the water section denoted by 100, the distance of the centres of gravity of the entire body, and of the immersed volume, represented by 13, the area of the section of the displaced volume denoted by 3600, and the angle of inclination 15°. From these assumptions he deduces the numerical values recorded in the two last columns.

Form of the Body.	Breadth of the Water Section.	Distance of the Centres of Gravity of the whole Body, and the immersed Volume	Area of the Section of the displaced Volume.	Angle of the Body's Inclination from the Perpendicular.	Numerical Value of G Z, or the Measure of the Body's stability.	Comparative Measure of the Weight, or Influence acting on the Sides of the Body at the mean distance of 30 from the Axis in Tons.
Sides of the vessel parallel to the plane of the masts above and below the water section.	100	13	3600	15°	2.84	56.8
Sides of the vessel above the water section projecting outwards 15°, and parallel to the masts below the same section	100	13	3600	15°	3.21	64 2
Sides of the vessel above the water section, inclining inwards 15°, and parallel to the masts below the same section.	100	13	3600	15°	2.53	50.6

Naval Architecture.

TABLE *continued.*

Form of the Body.	Breadth of the Water Section.	Distance of the Centres of Gravity of the Whole Body, and the immersed Volume.	Area of the Section of the displaced Volume.	Angle of the Body's Inclination from the Perpendicular.	Numerical Value of G Z, or the Measure of the Body's stability.	Comparative Measure of the Wind's influence acting on the Sails of the Body at the mean distance of 50 from the Axis, in Tons.
Sides of the vessel above and below the water section inclining outwards 15°.	100	13	3600	15°	3.59	71.7
Sides of the vessel above and below the water section inclining inwards 15°.	100	13	3600	15°	2.21	44.2
Sides of the vessel forming an isosceles wedge at an angle of 30°, its vertex immersed in the water.	100	13	3600	15°	2.86	57.0
Sides of the vessel forming an isosceles wedge at an angle of 60°, its vertex immersed in the water.	100	13	3600	15°	2.92	58.4
Sides of the vessel forming an isosceles wedge at an angle of 30°, its vertex above the water.	100	13	3600	15°	2.86	57.0
Sides of the vessel above the water section parallel to the masts, and inclining outwards 15° below.	100	13	3600	15°	3.21	64.2
Sides of the vessel above the water section parallel to the masts, and inclining inwards 15° below.	100	13	3600	15°	2.53	50.6
Sides of the vessel forming the uniform surface of a cylinder.	100	13	3600	15°	2.63	52.5
Sides of the vessel formed by arcs of a conic parabola.	100	13	3600	15°	2.81	52.8

(170.) The numbers which give the measures of the comparative stabilities afford some interesting materials for examination. A comparison of numbers 2 and 9, of 3 and 10, and of 6 and 8 disclose the remarkable fact, that whether the sides which spring from the water section, incline outwards *above*, or outwards *below*, the measure of the stability is the same; or whether the sides incline inwards *above*, or inwards *below*, the stabilities are still equal to each other. Whether the transverse section be, moreover, a rectangle, an isosceles wedge having its sides inclined to each other 30°, and with the vertex either above or below the water's surface; or whether the same section be a conic parabola, the measures of the stabilities are identical. The diligent inquirer may draw from the same Table other important information. Such are the curious and interesting results which even a brief examination of the subject affords. To the Papers of Atwood we would add the masterly Treatise of Dupin read before the Institute of France, and enriched by all the resources of Modern Geometry. It is a subject which the Naval architect should delight to dwell on, as one replete with the deepest interest, and lying at the foundation of his noble profession; which opens, moreover, an immense field for the finest applications of analysis, discloses relations of a singularly curious kind between forms and specific gravities, and in every point of view deserves an attentive philosophical examination.

Naval Architecture.

(171.) To those of our readers who may, however, be unable to follow Mr. Atwood through the analytical investigations necessary for computing these various stabilities, the same may be prosecuted experimentally, and a method for doing it may be seen in the *Annals of Philosophy* for 1824. A reference to Colonel Beaufoy's Tables will show how closely the results of experiment approximate to those of theory. Beaufoy's experiments.

(172.) But we must hasten to its application to ships, the main and essential object of this Treatise. It is a fundamental position that the resultant of the force which the water exerts in supporting a ship, and in resisting its tendency to heel, passes through the centre of gravity of the displacement, and that the direction of this effort is at right angles to the water's surface. It is for this reason a vessel, free and at rest, must have its centre of gravity in the resultant of the force of the water which supports it. When the ship heels, there is a tendency arising from the vertical pressure of the fluid acting upwards on the side of the vessel which is most immersed in the fluid to restore it to the position it had when at rest. The amount of this force is to be regarded as the measure of the stability. Application of the subject to ships.

(173.) Whenever a ship is inclined in the sea from an upright position, a prismatic solid is emerged on one side, to be denoted in the present investigation by E, and another prismatic solid immersed on the other, which we shall represent by I. These two solids, however dissimilar they may be from the peculiar figure of the ship, must of necessity be equal, the volume of the displacement remaining unaltered. The solids, moreover, being formed by the mutual intersection of two planes, one of which is the load water plane when the ship is floating upright, and the other a load water plane when she is inclined, the intersection must of necessity be a right line. From the circumstances, also, which influence the motion of the ship, this line must, moreover, be parallel to the axis of rotation, which is a right line passing through the centre of gravity of the vessel from head to stern. Let the line separating the immersion from the emersion be therefore denoted by x. Let G (pl. i. fig. 5) also be the centre of gravity of the whole ship, F that of its displacement when the ship floats upright, and Q the representative of the same point when the ship is laterally inclined. Let Q T V M Solids of immersion and emersion produced by the inclination of the ship. Investigation

Naval Architecture.

be a vertical line passing through the centre Q; and through F and G draw F T and G V at right angles to Q M, and through G draw G O parallel to Q M, intersecting F T in O.

(174.) Since, by the heeling of the ship, the volume E is taken from the displacement on the one hand, and I, which is equal to it, is added to the displacement on the other, the bulk of each volume being supposed to be concentrated in its centre of gravity, the former volume may be conceived to be transferred to I. The horizontal distance of the centres of gravity of the two volumes being denoted by b, the moment resulting from the translation of E will be b E, or b I.

(175.) Now when by the action of the wind the ship is made to heel through the angle A S a, or its equal F G O, the buoyant power of the fluid is transmitted upwards through the line Q M, with a force equivalent to the weight of the ship, or its equal the displacement D. The effort, therefore, made to right the ship, or to make it turn round a longitudinal axis passing through G, is proved by Atwood to be

$$\mathrm{D} \times \mathrm{GV} = \mathrm{D} \times \mathrm{FT} - \mathrm{D} \times \mathrm{FO}.$$

And since D × F T is the horizontal moment of the displacement in consequence of the removal of E to I, it is equal to the horizontal moment of E, that is to b I. Hence the preceding expression becomes

$$\begin{aligned} \mathrm{D} \times \mathrm{GV} &= b\mathrm{I} - \mathrm{D} \times \mathrm{FO} \\ &= b\mathrm{I} - \mathrm{D} \times \mathrm{FG} \times \sin \mathrm{FGO}. \end{aligned}$$

And if we represent F G by a, and the sine of the inclination of the vessel, or F G O, by s, we shall obtain the general formula

Formula of Atwood for stability.

$$\mathrm{D} \times \mathrm{GV} = b\mathrm{I} - \mathrm{D}as \ldots\ldots (\mathrm{I.})$$

(176.) This theorem, which is due to Atwood, enables us to find the stability of a floating body, whether that body be symmetrical with regard to the axis of motion, as is always the case in a ship, or whether symmetry of form does not exist, or the body be homogeneous, or the contrary. It is from this formula that Atwood derived the various positions of the floating parallelopiped before alluded to.

(177.) The line separating the volumes I and E must evidently be a right line, being formed by the intersection of two planes, that of the load water line when the ship is upright, and that of the load water line when the ship is inclined. This line, moreover, must be parallel to the axis of rotation, or to a right line passing through the centre of gravity of the ship, from head to stern. Let therefore the line separating the immersion from the emersion be denoted by x, and a longitudinal plane be supposed to pass through it, perpendicular to the water's surface. Suppose also Z to denote any section A S a of the solid I, perpendicular to x, and let z be the corresponding section B S b of the emerged solid E. Moreover let W, w be the horizontal distances of the centres of gravity of the sections Z and z from this longitudinal vertical plane. Then by the ordinary principles of Mechanics, we shall obtain

$$\frac{\int \mathrm{ZW}\,dx}{\mathrm{I}}$$

for the horizontal distance of the centre of gravity of the immersed solid I from that plane, and

$$\frac{\int z w\,dx}{\mathrm{E}}$$

for the horizontal distance of the centre of gravity of the emerged solid E from the same plane. Hence

$$b = \frac{\int \mathrm{ZW}\,dx}{\mathrm{I}} + \frac{\int z w\,dx}{\mathrm{E}};$$

or since by the conditions of a floating body I = E, we shall further obtain

$$b = \frac{\int \mathrm{ZW}\,dx + \int z w\,dx}{\mathrm{I}},$$

or $$b\mathrm{I} = \int \mathrm{ZW}\,dx + \int z w\,dx.$$

Consequently the general expression denoted by (I.) will become

Another expression of the same.

$$\mathrm{D} \times \mathrm{GV} = \int \mathrm{ZW}\,dx + \int z w\,dx - \mathrm{D}as \ldots. (\mathrm{II.})$$

which is another expression for the stability of a ship.

(178.) This formula is susceptible of some modifications by supposing the heeling of the vessel to be evanescent. In this case by denoting the half breadth of the ship at the water' surface by y, we shall have

$$\mathrm{Z} = z = \frac{y \times sy}{2} = \frac{sy^2}{2},$$

and $$\mathrm{W} = w = \frac{2}{3}y;$$

and the general formula (II.) becomes

Another form for the preceding formula.

$$\mathrm{D} \times \mathrm{GV} = \frac{2}{3}\int sy^3\,dx - \mathrm{D}as \ldots. (\mathrm{III.})$$

If the indefinitely small angle be regarded as constant, this last expression for the stability becomes

$$\frac{2}{3}\int y^3\,dx - \mathrm{D}a.$$

When the displacement is given, the stability is measured by

$$\frac{\frac{2}{3}\int y^3\,dx}{\mathrm{D}} - a,$$

which is the case when two ships of equal displacement are inclined at some small constant angle.

Formula for the metacentre.

The function $$\frac{\frac{2}{3}\int y^3\,dx}{\mathrm{D}}$$

is the height of what is commonly called the metacentre above the centre of gravity of the displacement. In this case the stability will be measured by the height of the metacentre above the centre of gravity of the ship.

(179.) In any case where the centre of gravity of displacement might coincide with the centre of gravity of the ship, the value of a becomes zero, and the stability at any small angle of inclination will be

Formula for any small angle of inclination.

$$\frac{2}{3}\int sy^3\,dx,$$

and supposing this small angle to be constant, we shall have

$$\frac{2}{3}\int y^3\,dx \ldots\ldots\ldots (\mathrm{IV.})$$

The latter formulæ must be employed with caution.

(180.) These latter formulæ, however, must be employed with caution, and in no case can they be relied on as measures of the stability, excepting at the very instant when a ship begins to heel. In the case of an

Naval Architecture.

ordinary inclination of five or ten degrees, the relation of the stabilities in two separate cases might be very different from what the formula (IV.) would give, when the centres of gravity of the whole ship and the displacement coincide; or what may be derived from the preceding formula (III.) when the centre of gravity of the ship is higher than that of the displacement. For in either case the values of W, w, might neither be equal to each other, nor to $\frac{sy^s}{2}$; and the values of Z and z may also very much differ from $\frac{2y}{3}$.

Example to prove the necessity of caution.

(181.) By way of illustration, suppose two vessels, A and B, figs. 6 and 7, to be so constructed, as to have identical load water lines, and the centres of gravity of the whole ship and the displacement to coincide; the sides of one of the vessels falling out above and below the water's surface, and the sides of the other falling in. Now, although the most ordinary mechanic must at once perceive that the stabilities of these bodies are not the same; and that the same impulse of the wind on equal masts and sails may in the two cases produce very different effects,—in one instance producing perfect security, and in the other extreme danger,—yet according to formula (IV.) the stability of each will be the same. Thus may the Naval Architect who is really desirous of advancing his art, draw from these analytical forms, motives for caution; and, moreover, learn, that although formulæ may sometimes be sanctioned by high names, and for a long time be current in the world, yet unless founded on legitimate facts and on that unyielding Geometry which allows nothing to escape its power, they ought at once to be rejected, or received only as approximations, until others founded on better principles can be found.

A single computation of the stability at one angle not sufficient.

(182.) It is not a single computation of the stability at one given angle, that can satisfy the desires of the scientific ship-builder. It must be found for three or four angles of heeling, as 2°, 5°, 7°, 9°, &c., in order to satisfy him whether the vessel he is about to construct has a sufficient stiffness at each successive angle, and whether at the same time she performs her motion of rolling with ease. In such a case some fine and approved model of the same class is commonly selected as a standard, in order to assist the constructor in his conceptions. A Naval Architect well acquainted with the details of his profession, may even from the principal dimensions and form of the sides between wind and water, make a tolerable estimate of the vessel's stability, by knowing the principal dimensions and form of the sides between wind and water.

To deduce from formula (II.) the actual stability.

(183.) But to deduce at once from the general formula

$$\int W Z\, d x + \int w z\, d x - D a s$$

the actual stability of a vessel, some angle of heeling, or inclination must be fixed on. Suppose, for example, it be 9°, and that an inclined load water plane be drawn, forming transversely with the horizontal plane of the same kind an angle equivalent to this quantity. In the great majority of cases, the solids of immersion and emersion formed by these planes will not be equal, their common intersection, excepting in particular constructions, falling on the lee side of the middle of the load water line. Hence an interval of $\frac{2}{10}$ or $\frac{3}{10}$ths of a foot is assumed on one side of the middle point of the load water line on the body plan, for the intersection of the two planes.

How the solids of emersion and immersion may be computed.

(184.) To compute the solids of emersion and immersion recourse must be had to the sectorial areas formed by the vertical sections of the body with the solids here adverted to. Each of these sectorial areas may be regarded as made up of a triangle and a curvilineal space, the latter being without sensible error regarded as a parabolic area. Having computed the whole of the sectorial areas, the actual solidities of immersion and emersion must be computed by the proper formulæ.

What must be done if those solids are not found to be equal.

(185.) If the results of these computations should prove the solidities of immersion and emersion to be unequal, some other point must be assumed for the intersection of the inclined and load water lines, and the preceding computation repeated until the two solidities are found equal. To assist us in determining this point, let Δ represent the computed difference of the solids of immersion and emersion, and a the area of the inclined load water plane. Moreover, let x be the perpendicular distance of the true inclined load water line from that just assumed. Then it is manifest, that without any very sensible error $a x = \Delta$, and consequently, $x = \frac{\Delta}{a}$, both of which functions are known. Hence the value of the fraction $\frac{\Delta}{a}$ being set off at right angles to the load water line first assumed, will give the position of the true one, as required.

When an equality is found between them how the stability may be computed.

(186.) Supposing, therefore, the position of the true inclined load water line to be at length attained, we may proceed to the final calculation of the stability. The integral of the function $W Z\, d x$ may be obtained by means of the sectors already alluded to. The different values of Z and z necessarily result from that process of computation, and the values of W and w may be found as follows. Suppose S B D, fig. 8, to represent one of the sectors, S D the upright load water line, and S B that which is inclined. Joining D B will divide the sector into the triangle and supposed parabolic area before alluded to. Bisect B D in E, draw E C perpendicular to B D, and make E F equal to two-fifths of it. From E and F let fall E G and F H at right angles to S B. Then will two-thirds of S G be the distance of the centre of gravity of the triangle S D B from the point S, measured on the surface of the water; and S H will be the distance from the same point of the centre of gravity of the curvilineal area D B C. Hence

$$\frac{2}{3} SG \times SBD + SH \times BCD$$

will give the value of W Z for this sector. And thus may the value of W Z be found for every sector. The application of one of the formulæ for equidistant ordinates hence determines the integral of $W Z\, d x$.

(187.) A like method is pursued in determining the integral of the same function when its elements are made to represent the more curved parts of the immersion that lie near the stern post and stern. In a similar manner the value of $\int w z\, d x$ may be found.

(188.) With regard to the remaining function $D a s$, the value of the displacement D has been already computed, and s is known from the fixed inclination of the vessel. The element a, depending on the true position

Naval Architecture.

of the centre of gravity of the vessel, can only be found by rigorous calculations, which we shall hereafter explain, or by reference to another ship of the same kind. Hence the value of all the functions constituting the second member of the equation

$$D \times G V = \int Z W\, d x + \int z\, w\, d x - D\, a s$$

are known, and thus the true measure of the stability is obtained. Let it be borne, however, in mind, that tedious as the processes of calculation may be found, the constructor must repeat them, until he finds at every reasonable inclination, that the stability is neither too small nor too great, and that the changes produced by rolling are such as shall satisfy both him and the gallant men who may hereafter navigate the vessel on the sea.

Actual computation.

(189.) The first step in the computation we shall illustrate is that of the solidities of immersion and emersion. Each of these will be divided as before into the middle body, the fore body, and the after body, these several parts being calculated by means of the proper formula.

To find the Content of the Immersion when heeled to 9°.

To find the content of the immersion.

AREAS OF THE SECTIONS IN THE MIDDLE BODY.

Extreme Areas.	Second Class of Areas.	Third Class of Areas.
1..24.47	4..42.16	2..33.23
28..31.19	7..46.75	3..38.46
55.66 = S	10..49.61	5..44.40
	13..50.31	6..45.79
	16..50.31	8..47.87

		26..43.62
		27..39.12
		840.36
		3
		2521.08 = 3 Q

and since $\frac{3\,i}{8} = 2.25$, we shall have

$$(S + 2\,P + 3\,Q)\frac{3\,i}{8} = (55.66 + 770.70 + 2521.08) \times 2.25 = 7531.74,$$

which is the solid content in the middle body.

AREAS OF SECTIONS IN FORE BODY.

To find in the next place the solidity of the fore body we shall employ the formula

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3}.$$

Extreme Areas.	Even Areas.	Odd Areas.
1..31.19	2..27.57	3..22.37
7.. 0.03	4..17.09	5..10.83
31.22 = Σ	6.. 3.79	33.20
	48.45	2
	4	66.40 = 2 s
	193.80 = 4 S	

and since $\frac{i}{3} = \frac{2}{3}$, the sections here being now supposed two feet apart, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (31.22 + 193.80 + 66.40) \times \frac{2}{3} = 194.28,$$

which is the solid content in the fore body.

AREAS OF SECTIONS IN AFTER BODY.

In like manner, by applying the same formula to the after body, we shall have

Extreme Areas.	Even Areas.	Odd Areas.
1..24.47	2..22.93	3..18.32
7.. 0.04	4..12.71	5.. 5.66
24.51 = Σ	6.. 1.55	23.98
	37.19	2
	4	47.96 = 2 s
	148.76 = 4 S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (24.51 + 148.76 + 47.96) \times 0.61 = 134.9503$$

for the solidity in the after body. Hence the total amount of the solid of immersion will be 7860.9703 cubic feet.

To find the Content of the Emersion when heeled to 9°.

To find content of the emersion.

(190.) By a similar process of computation we shall obtain the solidity of emersion.

AREAS OF SECTIONS IN MIDDLE BODY.

Extreme Areas.	Second Class of Areas.	Third Class of Areas.
1..17.19	4..39.79	2..25.99
28..24.37	7..40.40	3..31.34
41.56 = S	10..51.71	5..45.73
	13..52.42	6..48.40
	16..52.42	8..50.67
	19..52.42	9..51.33
	22 .51.42	11..52.42
	25..44.49	12..52.42
	394.07	14..52.42
	2	15..52.42
		17..52.42
	788.14 = 2 P	18..52.42
		20..52.29
		21..52.22
		23..49.65
		24..48.43
		26..40.39
		27..33.72
		847.68
		3
		2543.04 = 3 Q

and since $\frac{3\,i}{8} = 2.25$, we shall have

$$(S + 2P + 3Q)\frac{3\,i}{8} = (41.56 + 788.14 + 2543.04)$$

$$\times\ 2.25 = 7588.665$$

for the content in the middle body.

Areas of Sections in the Fore Body.

Extreme Areas.	Even Areas.	Odd Areas.
1..24.37	2..20.45	3..16.74
7.. 0.12	4..12.07	6.. 7.33
24.49 = Σ	6.. 2.68	24.07
	35.20	2
	4	48.14 = 2 s
	140.80 = 4 S	

and since $\frac{i}{3} = \frac{2}{3}$, the sections here being now supposed to be two feet apart, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (24.49 + 140.8 + 48.14)$$

$$\times \frac{2}{3} = 142.29,$$

which is the solid content in the fore body.

Areas of Sections in After Body.

In like manner for this portion of the emerged volume we shall have

Extreme Areas.	Even Areas.	Odd Areas.
1..17.19	2..14.05	3..10.16
7.. 1.98	4.. 7.63	5.. 3.58
19.17 = Σ	6.. 1.23	13.74
	22.91	2
	4	27.48 = 2 s
	91.64 = 4 S	

and since $\frac{i}{3} = 0.61$, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (19.17 + 91.64 + 27.48) \times 0.61$$

$$= 84.3569$$

for the solidity in the after body.

Hence the whole amount of the solid emerged by the heeling of the ship 9°, will be 7815.3119 cubic feet.

Computation of the function $\int Z\,W\,d\,x$.

(191.) Let us in the next place endeavour to obtain the value of $\int Z\,W\,d\,x$ for the three parts into which the immersed part is divided.

The values of Z W in the IMMERSION of the MIDDLE BODY are obtained as follows:

1..282.69	4..641.25	2..447.46
28..400.56	7..750.05	3..558.52
683.25 = S	10..803.92	5..691.93
	13..815.02	6..726.73
	16..815.02	8..773.11
	19..807.98	9..799.13
	22..801.99	11..811.13
	25..738.91	12..815.02
	6174.14	14..815.02
	2	15..815.02
	12348.28 = 2P	17..812.92
		18..809.03
		20..805.99
		21..803.04
		23..799.23
		24..783.74
		26..663.97
		27..562.86
		13293.85
		3
		39881.55 = 3 Q

Naval Architecture.

and since $\frac{3\,i}{8} = 2.25$, we shall have

$$(S + 2\,P + 3\,Q)\frac{3\,i}{8} = (683.25 + 12348.28$$

$$+ 39881.55) \times 2.25 = 119054.43,$$

which is the value of the integral $\int Z\,W\,d\,x$ in the MIDDLE BODY.

(192.) In the same manner, to obtain the values of Z W in the FORE BODY, we shall have

1..400.56	2..297.42	3..173.18
5.. 0.01	4.. 55.19	2
400.57 = Σ	352.61	346.36 = 2 s
	4	
	1410.44 = 4 S	

and since $\frac{i}{3} = 1$, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (400.57 + 1410.44 + 346.36)$$

$$\times\ 1 = 2157.37$$

for the value of the integral $\int Z\,W\,d\,x$ in the FORE BODY.

(193.) So also for the values of Z W in the AFTER BODY, we shall obtain

1..282.69	2..254.53	3..181.65
7.. 0.01	4..106.70	5.. 37.29
282.70 = Σ	6.. 4.60	218.94
	365.83	2
	4	437.88 = 2
	1463.32 = 4 S	

and since $\frac{i}{3} = 0.61$, there results

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (282.7 + 1463.32 + 437.88)$$

$$\times\ 0.61 = 1332.179$$

for the integral of $\int Z\,W\,d\,x$ in the AFTER BODY.

Hence the value of $\int Z\,W\,d\,x$ for the whole IMMERSED VOLUME will be 122543.979.

(194.) Proceeding in the same manner for the EMER-

SION, we shall obtain the following results for the values of $z\,w$ in the MIDDLE BODY.

1 . . 164.16	4 . . 580.42	2 . . 305.97
28 . . 280.47	7 . . 804.99	3 . . 461.88
444.63 = S	10 . . 869.36	5 . . 708.63
	13 . . 889.99	6 . . 771.27
	16 . . 890.09	8 . . 835.98
	19 . . 885.08	9 . . 857.22
	22 . . 858.23	11 . . 881.91
	25 . . 690.65	12 . . 888.67
	6468.81	14 . . 890.09
	2	15 . . 890.09
	12937.62 = 2 P	17 . . 889.72
		18 . . 887.48
		20 . . 883.61
		21 . . 880.69
		23 . . 819.02
		24 . . 778.57
		26 . . 591.53
		27 . . 457.05
		13679.38
		3
		41038.14 = 3 Q

and since $\frac{3\,i}{8} = 2.25$, we shall have

$$(\mathrm{S} + 2\,\mathrm{P} + 3\,\mathrm{Q})\frac{3\,i}{8} = (444.63 + 12937.62 + 41038.14) \times 2.25 = 122445.8775,$$

which gives the value of $\int z\,w\,d\,x$ in the MIDDLE BODY.

(195.) In like manner to obtain the values of $z\,w$ in the FORE BODY, there will arise

1 . . 280.47	2 . . 186.03	3 . . 99.04
5 . . 0.12	4 . . 30.47	2
280.59 = Σ	216.50	198.08 = 2 s
	4	
	866.00 = 4 S	

and since $\frac{i}{3} = 1$, we shall further obtain

$$(\Sigma + 4\,\mathrm{S} + 2\,s)\frac{i}{3} = (280.59 + 866.00 + 198.08) \times 1 = 1344.67$$

for the value of $\int z\,w\,d\,x$ in the FORE BODY.

(196.) And lastly, for the values of $z\,w$ in the AFTER BODY, there will be

1 . . 164.16	2 . . 121.42	3 . . 77.42
7 . . 0.12	4 . . 48.83	5 . . 22.55
164.28 = Σ	6 . . 3.15	99.97
	173.40	2
	4	199.94 = 2 s
	693.60 = 4 S	

and since $\frac{i}{3} = 0.61$, there will lastly arise

$$(\Sigma + 4\,\mathrm{S} + 2\,s)\frac{i}{3} = (164.28 + 693.60 + 199.94) \times 0.61 = 645.2702$$

Numerical value of this function.

for the value of $\mathrm{S}\,z\,w\,d\,x$ in the AFTER BODY.

(197.) Hence the value of $\int z\,w\,d\,x$ for the whole emerged volume will be 124435.8177.

Computation of the function $\mathrm{D}\,a\,s$.

(198.) Finally, to compute the value of the function $\mathrm{D}\,a\,s$, the amount of the displacement D has been found to be 104926.2, and s the natural sine of $9° = 0.15643$. Of the remaining element a it may be remarked that it is made up of two parts, one of which is the height of the centre of gravity of the vessel *above* the load water line, and the other is the distance of the centre of gravity of the displacement *below* the same line. The first of these quantities, by a comparison with another ship of the same kind, is found to be 0.93 feet, and the value of the latter we have calculated to be 7.56 feet. Hence $a = 0.93 + 7.56 = 8.49$ feet, and $\mathrm{D}\,a\,s = 393151.5104$, and the general expression

Whole value of the stability.

$$\mathrm{D} \times \mathrm{G\,V} = \int \mathrm{Z\,W}\,d\,x + \int z\,w\,d\,x - \mathrm{D}\,a\,s = 107628.2863,$$

which is the numerical measure of the stability at an inclination of 9°.

(199.) By some, the preceding computations may be regarded as tedious, and they may prefer Bouguer's formula $\frac{2}{3}\int y^3\,d\,x$ before alluded to, on account of its greater brevity; but let it be remembered, that no labour can be considered as too great, in order to secure to a ship of the humblest class the requisite stability. The history of ship-building unfortunately presents too many instances of ships having been constructed with insufficient stability.* M. Romme, for example, in his *Art de la Marine*, has adduced the remarkable instance of the French ship *Le Scipion* of 74 guns. As soon as this ship floated in deep water, it was immediately apparent that she wanted stability, and to ascertain it, the guns were run out on one side, and run in at the other. The vessel in consequence heeled 13 inches; and by adding the weight of the men to the same side, she was afterwards brought down 24 inches. A difference of opinion, it appears, existed among the Naval engineers as to the cause of this want of stability; and that the error was not accidental, but arose from some faulty principle of construction, may be inferred from the circumstance that the same defect existed in two other ships of war, *L'Hercule* and *Le Pluton*. The chief engineer asserted that the requisite stability might be imparted to *Le Scipion* by altering the quality and disposition of her ballast. The original amount of ballast had been 84 tons of iron and 100 tons of stone; and by the new arrangement these were to be augmented to 198 tons of iron and 122 tons of stone. But as a ship of war does not admit of any alteration in the amount of her displacement to compensate for the additional weight of ballast, on account of the necessity which exists of keeping her ports at a proper height above the water, the stock of water with which the ship had been previously supplied, was diminished by 136 tons, the excess of weight of the new ballast over the old. This arrangement must have had the effect of lowering the centre of gravity of the vessel, and thereby of increasing its stability; but on trial it was found not

Frequent instances of ships constructed with insufficient stability.

* Chapman remarks, that in the year 1628, when the Wasa of 80 guns, *half cartauers*, or 24-pounders, sailed from Skeppsholmen to Stockholm, with only the three topsails, in a light South-West wind, intended for an expedition to the Baltic, this ship did not proceed further than Blockhusudden, or about fifteen or sixteen cables' length from Skeppsholmen, when it upset, and sank ten fathoms, so that all below the main cross trees was under water.

The Stora Crona, Swedish ship of 126 guns, upset in 1676 in tacking. The cause assigned was, that this operation was not performed with the care which the crankness of the ship required.

Naval Architecture.

to be sufficient, the decrease in heeling, measured on the vessel's side, amounting only to four inches. Other ineffectual attempts were made, but the requisite stability was not obtained, until a sheathing was applied to the exterior sides of the vessel from four inches to one foot in thickness, throughout the whole extent of the water line, and extending 10 feet beneath it.

Proof of error of formula with evanescent angles.

(200.) This memorable example affords, therefore, a convincing proof that the formula sometimes employed to represent the stability, and limited to evanescent angles of inclination, cannot be relied on in any way. There can be no doubt that before a timber was laid, the stability had been in some way or other computed, yet no one suspected a defect in this important element until the vessel was actually floating in deep water; and as a proof that the real cause of the error was not known, recourse was had to a change of ballast; nor was it until other remedies had been unsuccessfully applied, that "the remedy," to adopt the remarkable words of Atwood, "was stumbled upon by accident, rather than adopted from any knowledge of the principles by which the application of it might have been directed." It was reserved for Atwood to show that "an error in the form of the sides of the vessel was the principal cause of the defective stability,"* and affords another example of the slow steps by which sound and substantial knowledge advances.

Effect of motion on the stability.

(201.) The change which takes place in the vertical pressure of the water in which the ship is immersed, when there is any relative motion existing between the ship and the water, must have an effect on the amount of the stability, on account of that vertical pressure affording a measure for the stability, when it is multiplied into the distance at which it acts from the longitudinal axis passing through the centre of gravity. So the altered circumstances of displacement which take place by a ship passing from salt to fresh water, altering in some degree the position of the centre of gravity of the immersed volume, must, in like manner, influence the stability.

Positions of the metacentre in different ships.

(202.) The point M, fig. 5, is called the metacentre, and is very often referred to in discussions on ship-building. In the British Navy the height of the metacentre above the surface of the water, using in the calculation the main breadths, is generally less than 6 feet, and is least in the largest ships. In 18-gun-brigs it is 5.5 feet, and such vessels are by no means deficient in stability. In frigates of 36 guns it is nearly 6 feet. In the Leopard, a fourth-rate, it is 4.2 feet. In third-rates it is from 4 to 5.5 feet nearly. In the Howe, a first-rate of 120 guns, it is 3.7 feet. Bouguer, in his *Traité du Navire*, remarks, that the metacentre was above the centre of gravity, in the frigate La Gazelle, 4 or 5 feet; in ships of 60 guns from 6 to 7 feet; in ships of 80 or 90 guns, from 4 to 5 feet; and in ships of 110 or 120 guns, sometimes as little as 2 feet.

* As an evidence that the defect of stability in *Le Scipion* did not arise from a want of breadth in the principal section of the vessel, M. Romme asserts, that other ships of the same force, *Le Magnifique, Le Sceptre, Le Minotaur, L'Intrepide*, had breadths the same or rather less than *Le Scipion*, and yet carried their sail perfectly well. The constructor doubtless thought to please his eye by altering in some way the external figure of the vessel, and, to satisfy a whim, sacrificed her security.

On the Centre of Gravity.

Naval Architecture.

(203.) A knowledge of the position of the centre of gravity of a ship is necessary in order to assist us in establishing a true measure for the stability, and likewise for enabling us to trace all the interesting phenomena connected with the pitching and rolling of a vessel. A rude approximation to the position of this point will by no means satisfy the present wants of Naval Architecture; and we are glad to perceive an increased anxiety on the part of our ship-builders, to arrive at more exact information respecting its very important properties.

Centre of gravity of a ship

(204.) There are many difficulties in the way of determining the centre of gravity of the hull alone, before any preparations are made for fitting it for sea, and for storing it with all the terrible apparatus of war. A knowledge of its true position under conditions like these leads to many interesting results; but the question rises immeasurably in importance when the vessel puts on all the pride and circumstance of war,—with her masts and yards and rigging, her guns and vast variety of stores,—and the bodies too of her crew, destined gallantly to defend her. If we direct our attention for a moment to the hull, we shall find, that though the powers of Geometry may enable us to fix with very great accuracy the position of this point, that no general conclusion could be deduced from the same, on account of the great diversity of form which even ships of the same class present. This would have an influence, were the hull alone to be considered; but the many altered circumstances which even the smallest change in the external figure produces in the masts and their accompaniments, and all the important considerations connected with stores and stowage, proves the utter impossibility of laying down any thing like a precise and definite rule respecting the position of this point.

Difficulties in the way of determining the centre of gravity.

(205.) Wherever the point under consideration is, however, situated, three rectangular coordinate planes may be supposed to pass through it, and to one only of these three can we assign a fixed and certain position. Every vessel, whatever may be her figure, and however whim and caprice* may influence the design, is necessarily, both as regards figure and stowage, divided into two parts by a vertical longitudinal plane passing through the middle of the keel. This partial symmetry of form fixes, therefore, the centre of gravity of a vessel with regard to its breadth.

Three coordinate planes may pass through it.

(206.) Another consideration which will enable us to fix the position of this point with regard to the length of the vessel, may be gathered from the hydrostatical principle, that the centre of gravity of the whole body and of the displaced volume must be in the same vertical line; and that as every vessel, when equipped, possesses a *given* displacement, it follows that the centre of gravity of this volume determines the centre of gravity of the whole ship, with regard to the length. Independently of this, however, it would be impossible to fix, *à priori*, a transverse plane, having the moleculæ on each side of it precisely similar and equal.

Position of this centre with regard to the length.

(207.) With regard to the depth of the vessel, a vague and uncertain conjecture has sometimes fixed it

With regard to the depth.

* The history of ship-building proves that it is not uncharitable to say, that whim and caprice *do* sometimes govern the designs of ships.

in the load water section; but this, which at most can only be true of a few ships, is much too uncertain to allow us to repose on it with any thing like confidence. Various experimental methods have been proposed to ascertain this, but there is no method like that which the theory of moments presents us with, by assuming a convenient horizontal plane, and dividing the integral of all the moleculæ constituting the vessel, by the weight of the vessel itself. Such of our readers as are conversant with the Theory of Mechanics,—and every ship-builder ought,—will remember, that if any number of particles p, p', p'', &c., be situated on one side of a plane given in position, at the distances x, x', x'', &c.; and any number of particles π, π', π'', &c., on the other, at the distances X, X', X'', &c., then will the distance of the common centre of gravity of all the particles from the assumed plane be represented by the general formula

Theory of moments.

$$\frac{p\,x + p'x' + p''x'' + \&c. - (\pi X + \pi' X' + \pi'' X'' + \&c.)}{p + p' + p'' + \&c. \ldots + \pi + \pi' + \pi'' + \&c.},$$

the point being found on one side or other of the assumed plane, according as $p\,x + p'x' + p''x'' + \&c.$ is *greater* or *less* than $\pi X + \pi' X' + \pi'' X'' + \&c.$

How the method of moments may be applied to it.

(208.) We regret that our limits will not permit us to exhibit the whole process of this calculation, and that we must confine ourselves to a general description of results. It is usual in a case of this sort to assume the water's surface as the given plane, and to throw all the weights, whether fixed or movable, into two classes, one of which shall have every individual centre of gravity *above* the plane of flotation, and the other *below*. In this way we shall obtain the weights of such parts of the lower masts as are above the plane of flotation, the top masts, the top gallant masts, and necessary appendages, together with the yards and bowsprits, and likewise the distances of the centres of gravity of the individual masses above the plane of flotation. The former results would be so many values of p, and the latter of x. These values multiplied together will give the amount of the moment $p\,x$. In like manner must the weight of all the standing and running rigging be obtained, together with the distances of their respective centres of gravity from the plane before alluded to. These results will give values for p' and x', and hence the amount of the moment $p'x'$. So also the same elements must be obtained for the cables, hawsers, &c., particular attention being paid to the place of their stowage. The sails also when furled on their respective yards, and the spare sails as they are stowed in the sail-bins. The guns also, forming so very important a part of the computation, must have their entire weights estimated, with all their appendages, and also with the greatest care have the distances of their centres of gravity calculated from the assumed plane, after making every proper allowance for the curvature of the decks. In like manner the moments of the anchors, taken in their proper places of stowage, the boats, the furniture of all kinds, the men's bedding, as stowed in the nettings, together with the entire moment of the men estimated at their quarters: all these, together with any other moment which our limited space prevents us from enumerating, when collected together, will give the sum of the moments *above* the water's surface.

Moments above plane of flotation.

Moments below plane of flotation.

(209.) In like manner, proceeding for the moments *below* the water's surface, a very important object is presented by the hull, separated as it is by the plane of flotation, into portions *above* and *below* the water's surface. To find this with precision, however, every bend of timber must be taken in succession, and, however tedious be the process, the keel, the planking, the riders, the beams, the decks, the knees, whether of iron or wood, the shelf pieces, water ways, and all the numerous parts constituting the hull,—each individual weight, with the corresponding distances of their centres of gravity from the plane of flotation, must be found to obtain the absolute moment of the hull. The water, whether contained in tanks or casks, must be computed with the same minute attention to accuracy; and so also must the wood and coals, as stowed in bulk. The specific gravity of each separate kind of provision must be found, and which, by knowing the bulk of the same, and the position of the centre of gravity, will furnish the moment desired. In the same manner, the wine and spirits as stowed in the spirit rooms, the beer, the purser's slops, and the men's chests must have their respective moments found. The shot also, the powder in the magazines, the boatswain's, gunner's, and carpenter's stores, as deposited in their respective store rooms, each and all of these must have their moments determined.

(210.) To obtain the moment of the ballast, its absolute weight must first be found. This may be computed by subtracting the absolute weight of all the preceding articles from the total displacement. To discover its centre of gravity, a plan of the intended stowage must be carefully prepared, and the position of this point thence carefully deduced. Its distance below the plane of flotation, multiplied into the weight of the ballast itself, will give the required momentum.

(211.) These different numerical results, applied in their proper order to the formula before given, will furnish the distance of the centre of gravity of the vessel from the plane of flotation; and which will either be above or below, according as the funcion $p\,x + p'x' + p''x'' + \&c.$ is greater or lesser than $\pi X + \pi' X' + \pi'' X'' + \&c.$

Results of two examples.

(212.) The heights of the centres of gravity of two ships of the line, determined by this method, were as follows: Bulwark of 76 guns, $\frac{7}{10}$ths of a foot above the load water section; Ajax of 74 guns, $\frac{6}{10}$ths of a foot above the load water section. We ought to know with certainty and precision the position of the centre of gravity of every ship. No amount of labour can be too great for determining this important element.

More convenient modes may be adopted.

(213.) It is necessary, however, to be able to arrive at a knowledge of the same by means more ready and practical than that here alluded to. Instead of estimating the separate parts, and computing the individual moments, it may be useful sometimes to take a vessel as a mass, and determine her centre of gravity in her entire state. A method of Chapman's was applied by Captain Hindmarsh and Mr. Morgan to the Scylla of 18 guns, which we shall briefly describe. The ship floated in harbour perfectly quiescent, having all her weights balanced equally on each side. A large graduated quadrant, having a plumb line attached to its centre, was fixed in the main hatchway. The situations of the different guns were marked on the deck. The guns were then moved in the same transverse lines to the other side. The shot and hammocks were also transposed to the inclined side, and the crew, which in the first place were equally distributed, were likewise disposed there. The distances which all the transferred weights had been moved were then measured, the separate amount of those weights being previously known.

Experimental method of Chapman's.

Naval Architecture.

Under these circumstances the inclination of the vessel was carefully measured and found to be 6° 20′.

Chapman's formula.

(214.) Chapman devised a formula, by which the centre of gravity of a vessel under these circumstances might be obtained. Let each weight that has been transferred be multiplied by the distance it has been moved, and let the total amount of these momenta be divided by the total sum of the weights moved, and let N P, fig. 5, drawn at right angles to M F, be made equal to this quantity. Through N draw N Q parallel, and through P draw P Q perpendicular to $a\,b$. Then, by putting W to represent the total transferred weights in cubic feet of sea water, we shall obtain from the principles of Mechanics the equation

$$W \times NQ = D \times GV,$$

arising from the necessary equality existing between the momentum of the weights when the ship is inclined through a given angle, and the moment of the stability. Now by the formula for the stability

$$D \times GV = b\,I - D\,a\,s;$$

and since

$$W \times NQ = W \times NP \times \cos PNQ,$$

we shall have

$$W \times NQ \times \cos PNP = b\,I - D\,a\,s.$$

Hence

$$a = \frac{b\,I - W \times NP \times \cos PNQ}{D\,s},$$

furnishing in given terms the distance between the centre of gravity of the vessel and of its displacement.

(215.) In the practical case we have just adverted to, the transferred weights multipled into the distances they were respectively transferred, produced 264.5; and hence the preceding formula becomes

Application to the Scylla.

$$a = \frac{b\,I - 264.5 \cos 6° 20'}{D \sin 6° 20'};$$

or by further substituting for the elements b, I and D, we shall have

$$a = \frac{446.2 - 262.8}{50.85} = 3.6.$$

Now the centre of gravity of the displacement being 3.97 feet below the load water line, the distance of the centre of gravity of the whole ship below the same line will be $3.97 - 3.6 = 0.37$ feet.

(216.) At the time this experiment was performed, the Scylla had not her full complement of stores on board, her draught of water forward being 11 feet 6 inches, and abaft 14 feet 10½ inches. After her additional stores were taken on board, amounting to 33.4 tons, her draught of water forward was increased to 12 feet 6 inches, and abaft diminished to 14 feet 10 inches. The moment of these weights above the water line, estimated at the instant of sailing, was 193 tons, the height of the centre of gravity of the sails being taken as in a top-gallant breeze. The moment of the weights below this water line, at the time of the last experiment, was 401 tons; and hence

$$\frac{401 - 193}{494.4} = 0.42 \text{ feet},$$

giving 5 inches for the distance of the centre of gravity of the vessel below the water line at the time of sailing.

Mr. Barton's method.

(217.) Mr. Barton, Naval Architect, has proposed to run the whole or part of the guns aft, and to observe the new draught of water, together with the place of the guns moved. From these data and the draught of the ship he proposes to determine this centre.

Mr. Abethell's method.

Mr. Abethell, Assistant Master Shipwright at Sheerness, proposes to get rid of the difficulty of moving the weights, by attending to certain data when a ship is docked with the under side of the keel deviating from parallelism with the upper surface of the blocks, which is almost always the case. We may suppose, he says, by the falling of the tide in the dock, the after extremity of the keel to come first in contact with the blocks. Then as the tide continues to fall, the after body will be gradually forsaken by the water, and the fore part further immersed; a constant equilibrium being maintained between the total weight of the ship, and the pressure of the water against the immersed part of the body, until the moment the ship is aground fore and aft. At any intermediate instant, the ship may be considered as a lever of the second kind, of which the fulcrum is the transverse line or point of contact of the keel and after block, and the power and weight, the weight of the immersed volume and of the ship respectively, each acting in the vertical line passing through its centre of gravity. As we can by a ready calculation from the draught of the ship, discover its weight, that of the immersed volume, and the perpendicular distance of the line of pressure from the fulcrum, the distance of the vertical line passing through the centre of gravity of the ship is the only unknown quantity in the equation of moments to be determined.

(218.) Supposing A N, fig. 9, to represent the natural water line of the ship, and K L the water line just at the moment when the fore part of the keel touches the blocks; draw Q H through the centre of gravity of the volume K F M L perpendicular to K L, and F G parallel to Q H. Then supposing the whole displacement under its ordinary circumstances to be D, and that corresponding to K F M L to be d, and $GH = b$; if the line S E O be drawn parallel to Q H, at a distance G E from G equal to $\frac{b\,d}{D}$, it will as well as P B O pass through O, the centre of gravity of the ship.

Mr. Major's method.

(219.) Mr. Major has given an ingenious method for finding the centre of gravity of a ship. Let the vessel be heeled to the same constant angle, by two separate horizontal lines, applied at different heights in the plane of the masts. It will then be evident that the momenta of the forces resulting from the separate applications of the inclining forces must be equal, since the same constant force of stability represents them both. Let P and p represent these forces, and a, b the respective distances at which they act from the centre of gravity of displacement. Let Δ also be the angle of inclination of the ship from the perpendicular, and x the distance of the centre of gravity of the vessel from the centre of gravity of displacement. Then we shall obtain the following equation for the forces employed:

$$P(a - x)\cos\Delta = p(b - x)\cos\Delta,$$

and

$$x = \frac{P\,a - p\,b}{P - p},$$

determining in known terms the elevation of the centre of gravity of the whole vessel above the centre of gravity of the displacement.

Naval Architecture. Masts.

Naval Architecture.

On Masts.

(220.) Theory has done little towards informing us respecting the lengths and dimensions of masts; experience, the great nurse of the useful Arts, must here be our guide. The following Table is derived from Edye's *Naval Calculations*.

Dimensions of masts and yards.

Names of Masts, Yards, &c.		Dimensions.														
		120 Guns.			80 Guns.			74 Guns.			Razée 50 Guns.			52 Guns.		
		Length.		Diameter.	Length.		Diameter.	Length.		Diameter.	Length.		Diameter.	Length.		Diameter.

Positions of ships' masts with regard to the length.

(221.) The positions of ships' masts with regard to the length of a ship, exercises an important influence on her properties. The shifting of a mast often occasions important improvements in the sailing of a vessel. The next Table contains the positions of the masts in fractions of the ship's length, on the load water line, and are the best with which experience has furnished us.

Rate of the Ship.	Fore Mast.	Main Mast.	Mizen Mast.
120 guns..........	$\frac{1}{8}$	$\frac{20}{86}$	$\frac{20}{24}$
80 guns...........	$\frac{5}{44}$	$\frac{20}{36}$	$\frac{20}{24}$
74 guns	$\frac{5}{39}$ to $\frac{5}{43}$	$\frac{20}{35}$ to $\frac{20}{36}$	$\frac{20}{23}$ to $\frac{20}{24}$
Razée 50-gun ship..	$\frac{5}{43}$	$\frac{20}{36}$	$\frac{20}{24}$
52-gun frigate......	$\frac{5}{40}$	$\frac{20}{39}$	$\frac{20}{24}$
46-gun frigate	$\frac{5}{38}$	$\frac{20}{35}$	$\frac{20}{23}$
Razée Corvette of 26 guns	$\frac{5}{42}$	$\frac{20}{35}$	$\frac{20}{24}$
28-gun-ship.	$\frac{5}{39}$	$\frac{20}{35}$	$\frac{20}{23}$
18-gun corvette	$\frac{5}{43}$	$\frac{20}{36}$	$\frac{20}{23}$
18-gun-brig.	$\frac{1}{6}$	$\frac{2}{3}$	
10-gun-brig.	$\frac{5}{29}$	$\frac{20}{31}$	
Schooner.	$\frac{1}{5}$	$\frac{20}{31}$	
Cutter.	Mast $\frac{10}{25}$ of the length of the vessel on the load water line.		

Seppings' improved mast.

(222.) Sir Robert Seppings has invented a mast, at once distinguished for the beauty of the principle employed in its construction, and for its very great economy. According to this ingenious plan, the largest piece of timber required for a first-rate mast, is 40 feet long, and 10 inches square; whereas on the old plan, timber $22\frac{1}{2}$ inches diameter and 84 feet in length was required.

Its economy.

The mean expense stated by the officers of Deptford, Chatham, Portsmouth, and Plymouth Yards, for making a mast of a 74-gun ship, wholly of Riga timber, upon the old plan was £1246, and upon the new principle, of the same material, £306. In the instance of a 46-gun frigate, the cost upon the old plan is £631, and on the new £175. The whole saving in the main and fore-masts of 80 sail of the line would amount to nearly £100,000.

Exceeds old masts in durability.

(223.) It is also worthy of attentive consideration, that masts constructed upon the new principle, exceed in durability those of the old. The large timber required in the former plan, rendered it necessary to employ the yellow North American pine, in conjunction with the Baltic pine; a practice attended with the most disastrous consequences, since the mixing together of materials having different degrees of durability, limits the effective services of a mast to the least durable part of the materials of which it is composed. In the system of Seppings, *one sort* of wood only is employed, and therefore any decay arising from the improper admixture of materials is entirely removed.

Readiness with which it can be repaired.

(224.) The beautiful simplicity manifest in this mast renders also its repair or examination a matter of the greatest ease. In the event of any of the principal parts of a mast constructed on the old plan requiring to be replaced, full one-eighth of the mast was removed; but on the new system, independently of the facility with which the mast can be separated, not more than one-thirty-sixth part requires to be displaced.

Such masts can be inverted.

Another advantage resulting from the plan is, the being able to have either end uppermost. If a mast be wounded by shot or otherwise injured, and the damaged part can be housed below, the mast will frequently answer all the purposes required, by inverting it. Such an operation can be performed without removing any article essential to the construction of the mast. The facility, also, with which a mast may be fished or strengthened with iron instead of wood, deserves in the present instance an attentive consideration.

Mast can be sent abroad in separate pieces.

(225.) In the case of its being necessary to send a mast abroad, a vessel that can stow a piece of timber from 40 to 50 feet long, is equal to the conveying of a first-rate's mast in parts. The Blanche frigate of 46 guns, conveyed a fore mast for the Spartiate of 76 guns, in fragments, stowed upon her lower deck, which, on its arrival in South America, was with the greatest ease and convenience put together. In the old system, this service would require a ship equal to the receiving of a mast 140 feet long, and of proportionate dimensions; it being impracticable from the form and dimensions of the component parts, to be forwarded in pieces without the certainty of injury.

Description of a mast of a first-rate.

(226.) Fig. 1. plate ii. gives a side view of a first-rate's main mast, the second figure being a view on the foreside of the mast. Fig 3 is a section of the mast taken between A and B, fig. 1, and showing the equal and parallel arrangement of the parts composing the mast. The section denoted by fig. 4, exhibits the directions in which the treenails are driven, and fig. 5 denotes a similar thing respecting the ends. Fig. 6 shows the manner of disposing the treenails longitudinally. Fig. 7 is a section showing the method of fitting the bibbs. Fig. 8 is a sketch of the screw hoop. There being a tendency for the *outer* lips of the hoops to close before the inner, a piece of wood of a compressible nature must be placed between the lips at the outer part, in order to prevent it, as seen at W, fig. 8.

Mode of putting it together.

(227.) In putting the mast together, the butts are to be coaked with coaks 3 inches diameter and 6 inches long, as shown in fig. 2; and the four centre pieces forming the core or spindle of the mast, are to be treenailed together diagonally, as *e d*, figs. 4 and 6, by $1\frac{1}{2}$ inch treenails, placed 2 feet apart. Each pair of outer trees is to be fastened together, as shown at *i h* in fig. 4, with $1\frac{3}{8}$-inch treenails, driven about 2 feet apart. The whole of the mast is then to be connected together, as at *a b* and *c*, figs. 4 and 6, by through treenails $1\frac{1}{2}$ inch diameter, which are also to be placed at about 2 feet apart, care being taken that none of these treenails

come nearer to the outer butts than about 12 inches; and where they cross the treenails before driven, there must be a distance between them of about 6 inches. At the head and heel of the mast, fig 5, where the outer trees are tapered, ⅞ inch bolts are to be used instead of the treenails marked *i h*. The holes for the treenails are to be payed with mineral tar, as in those bored in the ship's side.

Necessary precautions.

(228.) Many precautions are necessary in putting the mast together. Great care is to be taken to bring the butts into close contact with each other; and moreover to place the outside butts in the same section, opposite each other, so as to be *exactly* under the middle of the hoops. The ekings, or arris pieces, are also to be butted under a hoop, and the butts are to be so spaced, as to give a good scarf to the outer butts of the mast. A chamfer is to be taken off the inner angle of the ekings, as shown in fig. 4; and the ekings themselves are to be screwed to the mast with screws, in addition to the hoops, if required. Nails are not to be used.

On the Sails of Ships, and on the Centre of Effort of the Wind on Sails.

Sails of ships.

(229.) The determination of exact and proper forms for sails is a problem of great importance in Naval Architecture. However admirable may be the properties of the hull, unless a proper regard be paid to the dimensions of the masts, and the disposition and quantity of the canvass with which they are covered, the vessel may be found not to possess any of the properties her projector fondly anticipated.

Effects of wind on the sails.

(230.) It is the impulse of the wind on the sails, which gives to a ship that headway which enables her to accomplish her destined voyage. This impulse evidently depends on the dimensions of the sails, so that a greater amount of canvass ought to produce an increased velocity in the ship. Hence sails are made as large as the other properties of the vessel will permit, but there are limits in every vessel, beyond which it would be dangerous to pass. In the following Table are recorded those dimensions of sails which the large experience of our seamen and Dock-yards seems to have sanctioned.

Dimensions of the principal sails.

The Dimensions of the Principal Sails.

Naval Architecture.

Positions of ships' masts with regard to the length.

(221.) The positions of ships' masts with regard to the length of a ship, exercises an important influence on her properties. The shifting of a mast often occasions important improvements in the sailing of a vessel. The next Table contains the positions of the masts in fractions of the ship's length, on the load water line, and are the best with which experience has furnished us.

Rate of the Ship.	Fore Mast.	Main Mast.	Mizen Mast.
120 guns	$\frac{1}{8}$	$\frac{20}{36}$	$\frac{20}{24}$
80 guns	$\frac{5}{44}$	$\frac{20}{36}$	$\frac{20}{24}$
74 guns	$\frac{5}{39}$ to $\frac{5}{43}$	$\frac{20}{35}$ to $\frac{20}{36}$	$\frac{20}{23}$ to $\frac{20}{24}$
Razée 50-gun ship	$\frac{5}{43}$	$\frac{20}{36}$	$\frac{20}{24}$
52-gun frigate	$\frac{5}{40}$	$\frac{20}{39}$	$\frac{20}{24}$
46-gun frigate	$\frac{5}{38}$	$\frac{20}{35}$	$\frac{20}{23}$
Razée Corvette of 26 guns	$\frac{5}{42}$	$\frac{20}{35}$	$\frac{20}{24}$
28-gun-ship	$\frac{5}{39}$	$\frac{20}{35}$	$\frac{20}{23}$
18-gun corvette	$\frac{5}{43}$	$\frac{20}{36}$	$\frac{20}{23}$
18-gun-brig	$\frac{1}{6}$	$\frac{2}{3}$	
10-gun-brig	$\frac{5}{29}$	$\frac{20}{31}$	
Schooner	$\frac{1}{5}$	$\frac{20}{31}$	
Cutter	Mast $\frac{10}{25}$ of the length of the vessel on the load water line.		

(222.) Sir Robert Seppings has invented a mast, at once distinguished for the beauty of the principle employed in its construction, and for its very great economy. According to this ingenious plan, the largest piece of timber required for a first-rate mast, is 40 feet long, and 10 inches square; whereas on the old plan, timber 22½ inches diameter and 84 feet in length was required.

Its economy.

The mean expense stated by the officers of Deptford, Chatham, Portsmouth, and Plymouth Yards, for making a mast of a 74-gun ship, wholly of Riga timber, upon the old plan was £1246, and upon the new principle, of the same material, £306. In the instance of a 46-gun frigate, the cost upon the old plan is £631, and on the new £175. The whole saving in the main and fore-masts of 80 sail of the line would amount to nearly £100,000.

Exceeds old masts in durability.

(223.) It is also worthy of attentive consideration, that masts constructed upon the new principle, exceed in durability those of the old. The large timber required in the former plan, rendered it necessary to employ the yellow North American pine, in conjunction with the Baltic pine; a practice attended with the most disastrous consequences, since the mixing together of materials having different degrees of durability, limits the effective services of a mast to the least durable part of the materials of which it is composed. In the system of Seppings, *one sort* of wood only is employed, and therefore any decay arising from the improper admixture of materials is entirely removed.

Readiness with which it can be repaired.

(224.) The beautiful simplicity manifest in this mast renders also its repair or examination a matter of the greatest ease. In the event of any of the principal parts of a mast constructed on the old plan requiring to be replaced, full one-eighth of the mast was removed; but on the new system, independently of the facility with which the mast can be separated, not more than one-thirty-sixth part requires to be displaced.

Such masts can be inverted.

Another advantage resulting from the plan is, the being able to have either end uppermost. If a mast be wounded by shot or otherwise injured, and the damaged part can be housed below, the mast will frequently answer all the purposes required, by inverting it. Such an operation can be performed without removing any article essential to the construction of the mast. The facility, also, with which a mast may be fished or strengthened with iron instead of wood, deserves in the present instance an attentive consideration.

Mast can be sent abroad in separate pieces.

(225.) In the case of its being necessary to send a mast abroad, a vessel that can stow a piece of timber from 40 to 50 feet long, is equal to the conveying of a first-rate's mast in parts. The Blanche frigate of 46 guns, conveyed a fore mast for the Spartiate of 76 guns, in fragments, stowed upon her lower deck, which, on its arrival in South America, was with the greatest ease and convenience put together. In the old system, this service would require a ship equal to the receiving of a mast 140 feet long, and of proportionate dimensions; it being impracticable from the form and dimensions of the component parts, to be forwarded in pieces without the certainty of injury.

Description of a mast of a first-rate.

(226.) Fig. 1. plate ii. gives a side view of a first-rate's main mast, the second figure being a view on the foreside of the mast. Fig 3 is a section of the mast taken between A and B, fig. 1, and showing the equal and parallel arrangement of the parts composing the mast. The section denoted by fig. 4, exhibits the directions in which the treenails are driven, and fig. 5 denotes a similar thing respecting the ends. Fig. 6 shows the manner of disposing the treenails longitudinally. Fig. 7 is a section showing the method of fitting the bibbs. Fig. 8 is a sketch of the screw hoop. There being a tendency for the *outer* lips of the hoops to close before the inner, a piece of wood of a compressible nature must be placed between the lips at the outer part, in order to prevent it, as seen at W, fig. 8.

Mode of putting it together.

(227.) In putting the mast together, the butts are to be coaked with coaks 3 inches diameter and 6 inches long, as shown in fig. 2; and the four centre pieces forming the core or spindle of the mast, are to be treenailed together diagonally, as *e d*, figs. 4 and 6, by 1½ inch treenails, placed 2 feet apart. Each pair of outer trees is to be fastened together, as shown at *i h* in fig. 4, with 1⅜-inch treenails, driven about 2 feet apart. The whole of the mast is then to be connected together, as at *a b* and *c*, figs. 4 and 6, by through treenails 1⅝ inch diameter, which are also to be placed at about 2 feet apart, care being taken that none of these treenails

Naval Architecture.

come nearer to the outer butts than about 12 inches; and where they cross the treenails before driven, there must be a distance between them of about 6 inches. At the head and heel of the mast, fig 5, where the outer trees are tapered, ⅞ inch bolts are to be used instead of the treenails marked *i h*. The holes for the treenails are to be payed with mineral tar, as in those bored in the ship's side.

Necessary precautions.

(228.) Many precautions are necessary in putting the mast together. Great care is to be taken to bring the butts into close contact with each other; and moreover to place the outside butts in the same section, opposite each other, so as to be *exactly* under the middle of the hoops. The ekings, or arris pieces, are also to be butted under a hoop, and the butts are to be so spaced, as to give a good scarf to the outer butts of the mast. A chamfer is to be taken off the inner angle of the ekings, as shown in fig. 4; and the ekings themselves are to be screwed to the mast with screws, in addition to the hoops, if required. Nails are not to be used.

On the Sails of Ships, and on the Centre of Effort of the Wind on Sails.

Naval Architecture.

Sails of ships.

(229.) The determination of exact and proper forms for sails is a problem of great importance in Naval Architecture. However admirable may be the properties of the hull, unless a proper regard be paid to the dimensions of the masts, and the disposition and quantity of the canvass with which they are covered, the vessel may be found not to possess any of the properties her projector fondly anticipated.

Effects of wind on the sails.

(230.) It is the impulse of the wind on the sails, which gives to a ship that headway which enables her to accomplish her destined voyage. This impulse evidently depends on the dimensions of the sails, so that a greater amount of canvass ought to produce an increased velocity in the ship. Hence sails are made as large as the other properties of the vessel will permit, but there are limits in every vessel, beyond which it would be dangerous to pass. In the following Table are recorded those dimensions of sails which the large experience of our seamen and Dock-yards seems to have sanctioned.

The Dimensions of the Principal Sails.

Figure illustrating centres of gravity and centres of effort.

(232.) In fig. 9, plate ii., we shall find the centre of gravity of the several sails, together with the centre of effort of the whole system of sails, for two first-rates; the Britannia's class denoted by the strong lines A, and the St. Vincent's class by the ticked lines B. The plates given by Edye on this subject deserve an attentive consideration.

On the Resistance of Fluids.

Splendid names connected with resistance of fluids.

(233.) This subject, lying at the very root of Naval Architecture, is very defective, notwithstanding the efforts made by the most transcendent minds for its improvement. We may mention the names of Newton, Huygens, Euler, Daniel Bernoulli, D'Alembert, Don Juan, Bouguer, Condorcet, Borda, Bossut, Chapman, and many others, to show that no ordinary interest must attach itself to a subject, which, independent of its many useful applications, has offered so many attractions of high scientific interest.

Properties of a ship divided into two heads.

(234.) In a general way it may be said, that the properties of a ship may be classed under two general heads with regard to the fluid on which it floats; *viz.* those independent of any change of situation, and those which are called into activity when the body is in motion. In the midst of the difficulties which attach themselves on all sides both to the theory and experimental elucidation of the subject, it is fortunate that the great elements on which the safety as well as the general efficiency of a ship depend, are to be found among the former, and may be estimated with certainty and correctness; while those which relate to the form most essential to velocity, and which though not essential, are nevertheless of the greatest relative importance, are invested with the greatest difficulties, and to be found among the latter. Should the progress of knowledge at any future time disclose to us the real functional equations on which this important subject depends, Naval Architecture will make a greater and more decided step than it has ever yet done.

General circumstances on which the resistance to ships depends.

(235.) Our limits will not permit us to pursue this subject into its varied and beautiful details, and we must, therefore, content ourselves with recording generally, in the words of Dr. Inman, the circumstances on which the resistance to ships moving with the same velocity seem to depend:

First, on the area of the midship section, as causing a greater or less displacement of fluid by the motion of the ship.

Secondly, on the form of the fore body, as causing more or less additional resistance from the motion of the ship, considering only the inertia of the particles displaced; that is, supposing the void space left astern in consequence of this displacement to be instantly filled again by the fluid.

Thirdly, on the form of the after body, as causing a greater or less diminution of pressure forward, on account of the motion of the ship alone.

Fourthly, on the shape of the whole body, as affording a more or less easy and rapid transit of the displaced fluid to the stern, or to the void space, which would otherwise be left behind the ship for an instant.

Fifthly, on the form of the whole body, with respect to direction and the quantity of superficies, as causing more or less friction, and more or less adhesion of the fluid.

On the Stowage of Ships.

Stowage, its importance.

(236.) The best constructed ship may be so badly stowed, that she may fail to gratify in any way the ardent expectations of her constructor.* On the other hand, an experienced seaman, intimately conversant with

* The Thunderer 84, recently commissioned, affords an example. Built after the best model, as is understood, yet when commissioned by that thorough-bred sailor Captain Wise, and stowed exactly accordant to the plans and directions furnished to him, she was found entirely to fail. After leaving Sheerness, she took in 90 tons of additional ballast; and on her arrival at Malta, she was entirely restowed.

Naval Architecture.

the mechanical effects of stowage, may correct many of the errors of a badly formed vessel. Hence an attentive consideration of the effects of stowage is of the greatest importance to Naval Architecture.

Stowage applied to movable weights.

(237.) By the stowage of a ship is meant the disposition of her ballast and stores. Many of the weights in a ship, are necessarily fixed by circumstances, and it is, therefore, only to the movable weights, the ballast, and part of the stores, that any inquiries respecting the effects of stowage can be applied.

Stores and ballast.

(238.) The quantity of stores and ballast in a ship is one of the very first elements in the great problem of stowage.* This must depend on the class of vessels, and the service for which they are intended. As a general principle it may be remarked, that no ship should be incapable of stowing four months' provisions, with the necessary complement of stores. There can be no doubt that some improvements might be made in the forms of ships, so as to diminish considerably the amount of ballast. The degree in which this can be done, must be ascertained by experiment.

Many elements of a ship connected with stowage.

(239.) There are many elements of a ship intimately connected with the stowage. Among these may be mentioned the stability, rolling, pitching, scending, preserving a steady course, ardency, or tendency to fly up to the wind, going about, action of the rudder, and the strain of the materials.

In what way it influences the stability,

(240.) On the stability, the stowage exercises an influence, on account of the ballast and the movable weights governing in a great measure the position of the centre of gravity, which is an element intimately connected with it. When the stability requires to be augmented, it is necessary that the ballast should be distributed as low as possible; and the nearer it can be brought to the middle parts of the ship, the lower it will be. The form of the bottom of the vessel must exercise an important influence here, and shows how intimately the stowage is connected with the principles of construction.

the rolling,

(241.) The influence of stowage is, also, very considerable on the action of rolling. The skill of a Naval officer is displayed, when by changing the movable weights he is enabled to correct in any way the motion of rolling, and a similar remark may be made respecting the pitching and scending. We

pitching, and scending-

are, at present, much in the dark respecting the influence of stowage on these important elements; and very much that is done seems dependent more on accident than on rule. The sailor has abundant

The sailor can do much towards improving the stowage.

opportunity in these particulars to assist the Naval Architect; nor should the latter neglect the consideration of those apparently trivial causes to which the sailor often attributes the successful sailing of his vessel. The further the weights are removed from the centre of gravity, the greater is the resistance to quick and uneasy rolling; and to reduce the depth of the pitching and scending, as many of the movable weights as possible should be brought near the middle of the vessel. The practice of "winging the weights," as it is technically termed, is found to be fully justified by experience.

* It is an important problem, and has occupied the attention of the greatest Geometricians. The Academy of Sciences on many occasions directed the attention of Geometers to it. Among the great names connected with its history may be mentioned Daniel Bernoulli, Euler, the Abbé Bossut, J. A. Euler, and Bourdé de Villehaut.

Naval Architecture.

Yawing.

(242.) There is, sometimes, a disposition in a ship to turn from its direct course, increasing thereby the difficulty of steering, and more or less retarding the advancement of the ship. This among sailors is termed yawing. To correct any error of this kind, the movable weights should be so placed that their centre of gravity may be before the middle of the ship's length. The moment of the lateral resistance abaft the centre of gravity, will by this means be increased, and the moment forward diminished.

Mean direction of the water.

(243.) When a ship is completely stored and in perfect trim, the mean direction of the water passes a little before its centre of gravity; but since during the progress of the voyage there must have been a loss of consumable stores, the trim she originally possessed may be very much changed. The weatherly qualities, which made her the admiration of the seaman on leaving port, may either be lost altogether, or in a very great degree impaired. Hence the necessity of stowing the movable weights, so that the consumable stores being taken in proper proportions from the fore and after parts of the ship, the good qualities she originally possessed may be retained as her draught of water becomes successively decreased.

Consumable stores

Tacking.

(244.) In the case of tacking, the resistance a ship experiences in coming about depends on the lateral resistance of the parts before and abaft the centre of gravity. This resistance will be a minimum when the centre of gravity is in the middle of the length.

Resistance of rudder.

(245.) The power of the rudder to turn a ship being proportional to the distance of the centre of its mean resistance from the centre of gravity, the movable weights must be so placed that the centre of gravity of the ship may be before the middle of its length.

Weights of transverse sections and upward pressure corresponding.

(246.) With respect to the influence of the stowage on the materials composing the framework of the ship, too much attention cannot be paid to the relation between the weights existing in the several transverse sections of the ship, and the upward pressure of the water at the corresponding parts. The figure of the ship, and the unequal distribution of the weights, occasions at all times a longitudinal strain, producing arching, or as it is sometimes called hogging. To equalize, as much as possible, these actions, should be another great object of the Naval Architect; and although the necessary existence of great weights at the extremities, may prevent a perfect equilibrium with the buoyancy of the corresponding parts, as far as circumstances permit, attention should be paid to the placing of the weights where the buoyancy of the body is best able to sustain them. This requires the ballast and heaviest weights to be placed in the full parts of the body towards the midship section; reserving, however, the immediate vicinity of the main mast free from the heaviest weights.

Relation of the stowage to the qualities influenced by it.

(247.) Amidst these diversities, and apparently opposing qualities, it is, however, remarkable, as Mr. Morgan observes, that the modes of stowage required, by a due attention to the qualities influenced by it, are generally compatible with one another. The stability requires the greatest weights as low as possible, which accords with their concentration towards the middle of the length, a condition required to produce the best effect on the pitching, tacking, and strain of the materials. Holding a steady course, and the action of the rudder requires the weights to be placed so that the centre of gravity of the ship may be before the middle, but not so much as to be *practically* opposed to the

Naval Architecture.

consideration of its being very near to the middle, which reduces the resistance to coming about. The rolling requires the weights to be winged, which a skilful sailor knows how to manage without unduly raising the centre of gravity—an effect which would impair the stability. The result of all these conclusions is, that the movable weights in a ship should be so disposed, that its centre of gravity may be low and a little before the middle of its length; and that they should be winged as much as possible without raising the centre of gravity.

Experiments wanting.

(248.) A course of experiments on the quantity of ballast and the best disposition of weights, adapted to every class of ships, would be productive of great advantage to Naval Architecture. By determining, continues Mr. Morgan, the proper trim of the different classes of ships, much valuable information would be obtained for making designs. At the present time calculations depending on a supposed set of a ship in water have frequently to be altered. The time doubtless will come when this subject will be better understood.*

Rolling, Pitching, and Scending.

Rolling, pitching, and scending.

(249.) The action of the wind and the troubled surface of the sea destroy all those relations of equilibrium we have been hitherto contemplating, and new mechanical conditions, involving some difficult branches of analytical inquiry, are hence called into activity. The peculiar movements which these varied and uncertain forces occasion in a great volume like a ship, in so many different ways, have rendered an attention to this very important subject indispensably necessary. Not only do the rolling and pitching of a vessel, and those elevations and depressions which her whole body undergoes, intimately concern all who may be engaged in her navigation, and influence very materially all her sailing qualities, but the strength of the fabric of the ship itself, and the expense of her wear and tear depend greatly upon them.

Important consequences connected with them.

Easy movements of some ships.

(250.) Experience tells us, that among the innumerable ships which the enterprise of modern times has constructed, there are some which perform all their movements with ease and comfort to those who command them, and whose accidents and casualties, amidst all the uncertainty attending a seafaring life, amount to much less than many others of the same class. Of the Caledonia for example, it was said by her officers in their official communications, "*that she rolled in the trough of the sea quite easy*;" whereas, in the case of the Anson of 38 guns, which had originally been a 64, in her very first voyage the rolling was so excessive, that she sprang several sets of topmasts; and although endeavours were made to correct it by alterations in her masts and yards, she continued still to be a very uneasy ship, with an excessive wear and tear.*

Contrary properties of others.

Naval Architecture.

Examples of different ships

(251.) That there are innumerable intermediate stages of diversity between these two perhaps extreme cases may be gathered from many sources. Of forty 74-gun ships built nearly at one time from the same draught, and constituting a class by themselves, it was reputed that the Cressy, Blenheim, Armada, Poictiers, Conquestadore, Glocester, Rippon, and Clarence, rolled *tolerably easy* in the trough of the sea. The Leonidas and Shannon, 46-gun frigates built after the draught of the French Hebe, were said to roll *deep without jirking*; and of the 18-gun brigs, their rolling in the trough of the sea was stated to be *easy*. Of the 10-gun brigs, also, their rolling was said to be *middling easy*.

(252.) To inquire in some degree into the general question of rolling, is therefore one of vast interest to ship-building, and we regret that our exceedingly narrow limits can do little more than glance at its more prominent heads. Rolling may arise either from the impulse of a wave on the side of a ship, acting in some direction above her centre of gravity, or from the undulations of the waves themselves. Suppose, by way of example, A D B, fig. 1, pl. iii., to be a section of a ship, A B its load water line, E the centre of gravity of the whole ship, and G its metacentre. Suppose, also, B H to represent the direction of the impulse necessary to give it the inclination *a b*. The moment of the effort producing this inclination, will hence be in proportion to E H, and the moment of the effort tending to restore the vessel to its upright position, will be as the line E G. These efforts, acting in contrary directions, occasion rolling; the effect of the force producing it being as the sum of E H and E G. With regard to the undulations of the waves, a ship's rolling must commence the moment a wave rises on one side and sinks on the other. The inclination of the side of a wave is continually changing by imperceptible degrees,

What occasions rolling.

Example.

When rolling commences.

* The practical stowage of a ship depends principally on the master. When a ship is newly commissioned, this officer is directed by the Admiralty Instructions to obtain the most correct information he can of the manner in which the hold was stowed when she was last in commission, and what then were her qualities, that the stowage may be altered, with the sanction of the captain, if there be reason to suppose it may be done with advantage. If the ship have not been at sea, the master is then to consult the master shipwright of the Dock-yard. When the stowage of the hold is completed, the master is to enter in the log-book a particular account of the manner in which it is stowed, specifying the quantity of ballast in each hold, and the manner in which it is arranged.

* This ship was cut down in 1794; and Mr. Wilson of the Navy Office, a competent authority, remarks, "that although in all other Maritime States, the Science of Naval construction was well understood, yet so culpably ignorant were the English constructors, that this operation, so well calculated, when properly conducted, to produce a good ship, was a complete failure. Seven feet of the upper part of the top sides, together with a deck and guns, making about 160 tons, were removed, by which her stability was greatly increased; but by a complete absurdity, the sails were reduced one-sixth in area. Her masts and yards were afterwards increased to their original size, but as there was no decrease of ballast, she was very little improved."

Other sixty-fours were cut down, masted and ballasted in the same manner, and with similar results; and although they were improved by enlarging their masts and yards, they were still bad ships. A failure in this instance was indeed a national misfortune; for had Science been applied to their cutting down, a class of frigates might have been formed, capable in every way of coping with the large American frigates. The disasters of the late war might thus not merely have been avoided, but have been converted into events of quite an opposite character. Let those who decry Science, and check in every way its application to Naval Architecture, read in the pages of the last American war their utter condemnation. A very little Science would have enabled our Naval Architects at that time to have changed a ship of excessive stability, which must always be an uneasy one, into one of easy rolling. Instead of having reduced the masts and yards to those of a 38-gun ship, had they been a little increased, and at the same time half her ballast taken out, and her guns, moreover, changed for others of a larger caliber, instead of some of them being smaller, such a ship would have been easy, would have sailed better than any class of ships then in the Navy, and the expense of its wear and tear would not have exceeded the ordinary amount.

Naval Architecture.

Heeling of a ship round a longitudinal axis. Axis of rotation.

from a horizontal position to its greatest angle of inclination, and *vice versâ;* and therefore the force whose tendency is to turn the ship increases only by slow degrees; and long before she has arrived at that angle of rolling, which even a small inclination of the side of a wave would give, an opposing wave mounts on the other side of the ship, and prevents her further depression.

It sometimes rises,

(253.) There are many circumstances connected with the heeling of a ship round a longitudinal axis passing through its centre of gravity which it may be necessary very briefly to advert to. The axis of rotation (considered quiescent) round which the motion of rolling is performed, is far from maintaining at all times a constant elevation. In some cases it rises and in others falls, and sometimes, it is true, it remains the same. It has been found, for example, that when there is a tendency to immerse a greater solid below the water on one side than is raised above it on the other, the axis of rotation must rise during the inclination; and the reason is evident, since displacement on any other supposition would be increased, and a greater buoyancy exist than before, and consequently a greater buoyancy than the weight of the ship would balance. In such a case, whenever the motion of rolling is performed, the vessel must rise in heeling, and fall in righting again. On the other hand, if a rotation round the same axis (under similar quiescent conditions) immersed a less volume below the water than it raised above it, the same alternate rising and falling would take place, but in a contrary order; that is, the vessel would fall in heeling and rise in righting again.

and sometimes falls.

The same thing but in a converse order.

The amount of rolling depends on the centre of gravity of the ship.

Examples.

(254.) The existence and amount of this motion, which, according to the degree in which it prevails, must render the rolling of the vessel violent and uneasy, depend on the position of the centre of gravity of the ship, and on the form of the sides between wind and water. If we take the case of three vessels, each of which has its sides parallel to the plane of the masts as in fig. 2, 3, 4, plate iii., A B being the load water line in their upright positions, and $a\,b$ that when the vessel is heeled at an angle of 10°, G, the centre of gravity of the vessel, being supposed equally distant from the two water lines, coincident, moreover, with the surface of the water in the first position, below it in the second, and above it in the third. Then since in fig. 2 the immersion and emersion are equal, the vessel as it heels can neither rise nor fall; and as in fig. 3 the immersion is greater than the emersion, the vessel must rise in heeling; so in fig. 4 the immersion being less than the emersion, the ship will fall while performing the same motion.

(255.) If, however, the sides of these vessels are made to fall out above the load water line, some changes will be found to take place. In the case of fig. 2 the immersion will in this case exceed the emersion, and the axis of rotation, supposing it to remain quiescent, will rise. In the case of fig. 3 the immersion will exceed the emersion more than before, and a still greater rising in the ship take place than before; and in fig. 4 an increase of the immersion will also take place, and hence a decrease in the falling of the vessel. If, on the other hand, the sides of these vessels fall out below the water line, and preserve their parallelism above it, the ship denoted by fig. 2 will fall in heeling, the rising of fig. 3 would be corrected, and the falling of that denoted by fig. 4 increased. Wherever, therefore, there is a great disproportion between the immersion and the emersion, the axis of rotation being supposed quiescent, in large angles of rolling, the shocks resulting from the ship's rising and falling must be very great. To avoid such an important error in construction, it is necessary to find by computation the exact position of the ship's centre of gravity, and then to alter the body till the immersion and emersion caused by heeling round a quiescent longitudinal axis passing through that point are equal. A like attention must be paid to the pitching of a vessel; for any great inequality between the immersion and emersion round a quiescent axis would be attended with similar bad effects. The motions of rolling and pitching are hence most uniform and most free from sudden shocks, when the centre of gravity of the ship is in or near the plane of the load water line. Should circumstances not permit the centre of gravity to be brought into the plane of the load water line, it is proper to endeavour to bring it as near to it as possible. It may be further observed, that as the keel and the lower parts forward and aft contribute in a very great degree to diminish the rolling by the direct opposition of their surface to the water, the further these parts are removed from the axis of rotation, the greater will be the effect they produce in diminishing the rolling; and for this reason also, when the centre of gravity is in the plane of the load water line, the ship should roll less. The form of the ship, moreover, near the load water line will influence its motion also.

How shocks may be avoided.

When rolling and pitching are most uniform.

These motions illustrated by a pendulum.

(256.) These peculiar motions of a ship have been sometimes illustrated by the movement of a pendulum oscillating in the same time as a ship. If for example P, p, &c., denote the particles of a ship, and D, d, &c. their distances from the axis of rotation passing through the centre of gravity, the length of such isochronal pendulum will be

$$\frac{P D^2 + p d^2 + \&c.}{\text{whole ship} \times E G},$$

where E is the centre of gravity, in this case the centre of suspension, and G is the metacentre, on which the whole buoyancy of the fluid equivalent to the weight of the ship acts upwards. Supposing the functions $P D^2$, $p d^2$, &c. to be given as well as the weight of the ship, the length of the isochronal pendulum will vary inversely as E G; or in other words, that the greater is the elevation of the metacentre above the centre of gravity of the ship, the shorter will be the pendulum, and the quicker the vibrations of the ship; and on the other hand, the less that distance is, the slower will the rolling become. Supposing the line E G and the weight of the ship to be given, the duration of the vibrations will vary with the values of D, d, &c.; and the less those values are, the shorter will be the pendulum and the quicker the rolling; and on the contrary, the greater are the vibrations, the slower it will be. It must, however, be remarked, that the conclusions thus arrived at are absolutely true only when the vibrations are evanescent; but that they may be regarded as nearly true when they are in a practical sense very small. When a ship rolls through finite angles, the vibrations are very different from those of a pendulum of an invariable length, the point G not being then a fixed point.

Difficulty of constructing a ship that shall have proper stability and roll easily.

(257.) It is no easy matter to construct a ship which shall possess a proper stability and also, at the same time, perform her motion of rolling easily, although this is a point at which the Naval Architect should continually

Naval Architecture.

aim. It has been observed, that an undue attention to one of these properties has been obtained at the expense of the other. If the stability be diminished, the heeling of the vessel will be increased by the same amount of acting force; but the heeling as well as the righting of the vessel will be more slow and easy. The stability cannot, however, be diminished too much without endangering in a great degree the safety of the ship. On the other hand, while an increase of stability diminishes the heeling of the ship,—and which confined within proper limits produces wholesome effects; yet when carried to excess, the inclining force is so suddenly destroyed, as to produce shocks of the most dangerous kind. A wave acting on the side would produce a powerful effect, so that a ship thus constructed, would in the least sea be subject to continual and quick vibrations. It has been remarked by some writers, that the height of the metacentre alone determines the properties of a ship with regard to the qualities of its rolling; but it is possible that the height of this point may be something diminished, and yet the forms of the sides be so determined as to impart a stability sufficiently great. The height of the metacentre may, however, be increased beyond its usual limits, and, nevertheless, by injudicious alterations in the forms of the sides, the stability be found too small.

Summary calculations.

(258.) Inman recommends, in order to form a proper estimate of a ship's properties in this respect, to make accurate calculations of the stability at different angles of inclination, and to compare the result in each case with the stability of approved ships of the same class. Hence, also, he adds, that to enable the Naval Architect to design ships which may be expected to possess the requisite stability, he must be furnished not only with all the necessary calculations for the different kinds of ships already built, but also with a minute detail of their performances at sea. Thus we see how intimately blended are the pursuits of the Naval Architect and the sailor.

Greatest difficulty with merchant ships.

(259.) It is a much greater difficulty to determine the necessary relations between the stability and the rolling in merchant ships, than in those intended for the purposes of war. In the former class of vessels, the object is to obtain the greatest possible burthen, at the least possible expense of the ship. Hence vessels of this kind should be very full below, and have but very little height above the water in proportion to their breadth. The centre of gravity of the displacement will thus be very low, and consequently the metacentre also. Hence, also, the centre of gravity of the cargo must be brought as low as possible, to ensure the requisite stability. The result of all this is the quick rolling of the ship and violent shocks, which, however, may in some degree be diminished by winging the weights as much as circumstances will allow.

Remarks on centre of gravity.

(260.) Economy in the navigation of merchantmen requiring as small a number of men as possible, a less quantity of sail is rendered necessary, and hence a less distance between the centre of gravity of the vessel and its metacentre, a circumstance which, as we have before seen, makes the motion of rolling much easier.

(261.) Ships of war which have not occasion for so great an amount of capacity below, and require velocity, may be so constructed as to have their centres of gravity higher. The metacentre ought, therefore, to have such a height above the water, that the common centre of gravity of the ship and of the weights may be brought nearly to the plane of the load water line, and that the ship may still be sufficiently stiff in resisting heeling.

(262.) There is, however, another species of rolling which takes place with regard to the length, to which we must not omit to advert. In this case the extremities of the vessel rise and fall. The fore part of the ship being raised by a wave, it falls again when that wave has passed; and any motion thus imparted to a ship would very soon cease, did not another wave follow to raise the bow of the ship again. When a ship is close to the wind and meets the waves, it often happens after a sea has passed the fore part, that it suddenly falls and raises itself with difficulty upon the following wave, and in such a case the ship is said to *pitch*. When a wave has passed the fore part of the ship, and is arrived near the middle, a space of considerable dimensions is left void near the bows, and the ship there is left quite unsupported. The vessel, therefore, precipitates itself with a very great momentum, indicated by the product of all the weights in the fore part of the vessel, multiplied by their distance from the point at which the ship is unsupported. Sometimes the after part falls heavily, and the ship is said to *scend*. This results from a similar cause and has the same inconveniences. Both these motions very much impede the motion of the ship, the whole fabric of the masting undergoing the greatest shocks and strains. Every part of the body of the ship suffers also greatly, there being a constant tendency in all its parts to separate. This must occasion prodigious strains on all the fastenings, and calls for the greatest attention on the part of the Naval Architect.

Pitching.

Scending.

Fastenings.

(263.) This kind of motion, and all the resulting strains must hence be different in different kinds of ships. The same amount of fastening, therefore, which may be quite sufficient for one kind of ship may be altogether insufficient for another. In vessels which are very full near the load water line fore and aft, and very lean below, the pitching and scending are very great. Such a state may, however, in some degree be relieved by an attention to the distribution of the weights. The errors of the Naval Architect may be more or less corrected by the experienced seaman. It is manifest that when the weights in the fore part of the ship are carried near the middle, the effect of the ship's plunging in this part will be less; and not only must this motion become less quick, but succeeding waves will have less difficulty in raising it again; and a similar remark applies to the after part. Hence much relief may be afforded to these motions of a vessel by bringing the weights as much as possible in the neighbourhood of the middle of the ship. There are some weights which it is impossible to move, and which produce a great effect, such as the fore mast and its rigging, the bowsprit and its anchors. The mechanical effects of these the ship-builder must be prepared to resist by the figure and strength of his fabric.

Concentrating the weights.

Other motions.

(264.) There are motions, however, of another kind, intermediate between rolling and pitching, or rolling and scending, and which exercise an important influence on the movements of a ship. When a vessel floats quiescently on the surface of the sea, the centres of gravity of the displacement and of the whole ship are in the same vertical plane; but when the vessel is inclined, the latter point is carried to leeward, and the buoyancy of the water, acting upwards through it, endeavours to turn the ship back. The axis round which

Naval Architecture.

the ship revolves in such a case, must hence depend on the position of the centre of gravity of displacement. If this latter centre be in the transverse section passing through the centre of gravity of the ship, the vessel will revolve about an axis parallel to the length; but if it be either before or behind it, the buoyancy will cause the ship to revolve round an axis, occupying a place between the transverse and longitudinal axes of the vessel. Each different inclination may hence be accompanied by an axis peculiar to itself; and hence a system of movements may be produced tending to disunite all the parts of the ship, deranging its different adjustments, and operating greatly in retarding its progress.

How to counteract them.

(265.) To counteract motions so injurious as these, the centre of gravity of the displacement, both when the vessel floats upright, and when it is inclined at different angles of inclination, should at all times be found in the same vertical plane. This must be done by assigning to the volumes immersed or emerged in consequence of the inclination, such particular forms, that the line joining their centres of gravity shall in all cases be parallel to the transverse section. This important consideration, it appears, was first attended to in English ships by Dr. Inman. By comparing the reports made on different ships in his Majesty's Navy, with calculations made on their drawings, it appears that these vessels have the best character for regular and easy motion, *cæteris paribus*, that have this property.

On the Arching of Ships.

Arching of ships.

(266.) Our ordinary experience proves how difficult it is, in the simplest combinations of carpentry, to preserve precisely the figure that may have been intended; and the ingenuity of the workman is frequently taxed in devising braces and ties in order to maintain it. In a far greater degree is the Naval Architect called upon to devise means for preserving to a ship, when she is launched, the same figure she possessed when resting on her shores. To accomplish this demand a large share of practical knowledge combined with an acquaintance with the theoretical wants of Naval Architecture. The ingenious constructor cannot but be anxious that his ship should retain, when she sails in all the pomp and busy circumstance of war, and when innumerable strains are acting upon her, the properties he originally desired her to possess.

(267.) We can hardly imagine a more mortifying circumstance than to find, after every imaginable care has been bestowed upon a design, that the moment the vessel is launched, some of her essential conditions are altered, her hull exhibiting unequivocal signs of weakness, her extremities dropping, and her whole frame becoming arched. It is the business of theory not only to plan the ship, but to devise means for constructing her so that her exact theoretical form shall be preserved.

Combining of timbers a difficult subject.

There is more science in combining timbers together than is commonly imagined; and when we see how difficult it is, even in the simple fabric of a gate, a partition, or a roof, to preserve entirely the form that was intended, we cannot but observe in the larger and more complicated fabric of a ship how greatly the difficulty must be augmented. Here it is that theory and practice can do so much to aid each other. In all the mechanical arts they should be inseparably bound together, and yet how seldom are they thus allied! A narrow jealousy and mistrust too often divides them.

Naval Architecture.

Why peculiarly so in the case of a ship.

(268.) There are circumstances, moreover, of a very peculiar nature, which in the case of a ship contribute to produce this derangement of form, and which it is fitting the Naval Architect should be made intimately acquainted with. It is not only in a storm that her fastenings are disturbed, and her timbers exposed to different strains from those which they underwent when she was supported in the dock, but even when she floats in tranquillity in the harbour, destitute even of her masts, and her most ordinary stores. The simple hull itself is compelled to bend by the buoyancy of the very fluid on which it floats.

Cause of weakness.

If a straight line be drawn from the head to the stern, whilst the vessel is on the slip or in dock, no sooner has she entered her own element, than each end of this line will be found to have dropped from two to six inches, in consequence of the weakness of the fabric. In cases of arching, also, some of the butts of the planks are always found to have parted aloft, at the same time that the angular position of some parts of the structure has as uniformly been more or less altered; and very generally a certain degree of sliding is observable in the planks at the sides of some of the ports. This sliding was seen very distinctly by Dr. Young in the planks of the Albion and of the Belliqueux, at the same time there were also obvious indications of a certain degree of extension and compression. In the Albion the butts of the planks were parted so far, that in some instances pieces were let in between them; and in the Belliqueux there was a space of about five inches between the middle of the deck transom and the carling, which had originally been in contact with it. In the Asia, the arching amounted to three inches and a quarter, and the comparative length of the upper and lower parts was probably altered about two inches at most: the parting of the butts amounting to three-sixteenths of an inch each, "for upwards of fifty feet in length in the midships, and for about eight feet from the top side," making a total extension of probably less than an inch; so that about half the effect seems to have been produced in one way, and half in the other; but apparently the greater half by the want of stiffness. Some degree of permanent compression or crippling below has been observed, the butts of the planks opening when the cause of arching has been removed, and the sheathing being more wrinkled than would have happened from the simple bending of the planks.

To correct this was the problem undertaken by Sir Robert Seppings.

To correct these serious defects was one of the great problems undertaken by Sir Robert Seppings. Before his time, all the materials composing the fabric of a ship were disposed nearly at right angles to each other; a disposition not sanctioned by any authority, nor by the humblest maxim of mechanical knowledge. A ship too from its great length, and the peculiarity of its form, is the body calculated to display erroneous combinations in the most remarkable degree.

(269.) The length of a 74-gun ship being 170 feet or more, it requires but little knowledge of materials to perceive that planking of such a length, whatever be its amount of thickness, or the mode or way in which it is joined together, must under such a system bend with its own weight. The fastenings and connections of the several parts of such a fabric, cannot therefore but suffer from a want of stiffness, and a change of form must be the consequence.

(270.) The truth of the principle here adverted to is confirmed by every day's experience. The idle schoolboy racks the frame of his slate, loosening its fastenings,

Naval Architecture.

and deranging its figure; and the country carpenter finds, however he multiplies his *parallel* rails or bars, and whatever ingenuity he displays in their fastenings, the uniformity of his gate will soon be destroyed, unless he adds a brace or diagonal timber to his fabric. In a popular sense we may say the old system of timbering resembled in principle fig. 5, plate iii. and the new system fig. 6. It is obvious, to adopt the familiar language of Seppings, the greater the length of the frames, the greater will the superiority of the latter be shown.

Effects of a triangular combination of timber.

(271.) The effect of a triangular combination of timbers like this is, that the pieces disposed horizontally are acted upon as ropes by a strain of the fibre, whilst the other parts are pressed upon as pillars; or, in other words, the pressure acts in the direction of the fibres of the wood. In the old plan, and which, for distinction sake, may be denominated the rectangular mode, the fibres are acted upon transversely, or across the grain, just as a stick, when placed across the knee and pressed by the hands at each end, is first bent and then breaks. To prevent any transverse action upon the fibre of the timber, is one of the benefits arising from the new system, and to impede a longitudinal extension of the structure is another. For as the diagonal frame, composed of a series of triangles, aided by diagonal trussing between the ports, prevents the fabric from being acted upon transversely to the fibres of the materials horizontally placed, so the wales, the planking, the shelf pieces, the improved water ways, and the decks systematically secured, become the tie beams of the structure.

Resulting strength.

(272.) The great strength of the principle here adverted to is also to be contemplated in another point of view—that of rendering the strength of the fabric as general and united as possible. It is a trite maxim to observe that the strength of any body, let its construction be what it may, can never exceed that of its weakest part; but it is one, simple as it is, which has been too often lost sight of in the practice of ship-building. In the new system of Seppings, the openings between the ribs are filled in with slips of timber nearly to the height of the orlop, or lower tier of beams. These being calked and pitched over, make the frame from head to stern, and within a few feet of the greatest draught of water, one compact and water-tight mass of timber; so that were any of the outer planking of the bottom to be removed, the ship would not only continue to float, but would also be preserved from sinking. In the old system, the starting of a plank often proved fatal.

Other sources of strength.

(273.) The openings between the frame, where the width of the space does not exceed three inches, are filled up by driving in wedge-like slices of wood, one driven from the outside, the other from within, forming the parallel space of the opening, and bringing the parts into the closest contact. In the openings exceeding three inches, the space is occupied by corresponding pieces having their fibres laid in the same direction as that of the frame timbers. These fillings add not only to the strength and durability of the fabric, but preserve the health of the crew from the effects of the impure air arising from the filth which so soon collects in these openings, rendering the ship less liable to leakage, as well as facilitating the stoppage of any leak; and lastly increasing the thickness of the bottom from four or four and a half, the usual thickness of the plank, to about sixteen inches, thereby diminishing very considerably the danger to be apprehended from getting on shore, or foundering at sea.

Durability.

(274.) That this improvement promotes the durability of the ship may be inferred from what follows. In the first place, the openings in the old principle, after a ship has had any considerable length of service, are choked up in many parts with an accumulation of filth. Secondly, that no free circulation of air can be obtained in these openings by any means. In the third place, that timber being either freely exposed to, or excluded from the air, is equally preserved. And fourthly, that it has been found on examining the frame and plank of old ships, that those parts now filled in, generally decay sooner than the rest; *viz.* from the floor heads in the midships, and from the dead wood forward and abaft to the height of the orlop clamps.

Gain in the capacity of the hold.

(275.) With regard, also, to the gain in the internal capacity of the hold, it may be remarked, that though the trussed frame projects from the timbers five inches more than the thick stuff at the floor-heads,—yet, as in the old system, the perpendicular riders are brought upon the thick stuff, their projection into the hold is more by eight inches than that of the new, giving an increase of stowage in favour of the diagonal frame. Another important point is, that a tier of iron ballast may also be disposed of many inches lower, giving an increase of stability with less weight, and enabling the vessel to carry her ports higher out of the water.

Bird's-eye view of internal part of a seventy-four.

(276.) In pl. iv. fig. 1. is a bird's-eye view of the internal part of one side of a 74-gun ship in a complete state, the diagonal timbers intersecting the timbers of the frame at angles of about 45°. In the fore part of the ship these timbers are disposed in contrary directions to those in the after part, their distances from each other being from six to seven feet or more; their upper ends abutting against the horizontal hoop, or shelf piece, of the gun-deck beams, and the lower ends against the limber streaks, except in the midships, where they come against two pieces of timber placed in on each side of the keelson for the purpose of taking off the partial pressure of the main mast, which in all cases causes a lagging down of the keel, and sometimes to an alarming degree. Pieces of timber are next placed in a fore and aft direction over the joints of the frame timbers, at the floor and first futtocks heads, their ends being in close contact with and coaked or dowelled to the sides of the diagonal timbers. In this state the framework in the hold presents various compartments representing the forms of rhomboids. A truss timber is then introduced into each rhomboid with an inclination opposite to that of the diagonal timbers, thereby dividing it into two parts. These truss pieces, says Seppings, are to the diagonal frame what the key-stone is to an arch; for no weight or pressure on the fabric can alter its position in a longitudinal direction, till compression takes place at the abutments, and extension of the various ties.

Description.

Diagonal timbers.

Arch-like figure of it.

(277.) This arch-like property of the diagonal frame not only opposes change in a longitudinal direction, but also resists external pressure on the bottom, either from grounding or any other cause, because no alteration of figure can take place, without forcing the several parts of which it is composed into a smaller space. The connection kept up by means of the trussed frame firmly attached to the timbers of the ship by circular coaks and bolts, together with the shelf pieces united to the sides and to the several beams by means of the same sort of

fastenings, imparts such unity to the whole as to give to it an immense superiority over the old system it displaced.*

Shelf pieces.

(278.) The beams of the new system are disposed nearly as in the old, excepting that in midships, where a ship necessarily requires the greatest security, two additional beams have been introduced. All of them are attached to the ship's sides by shelf pieces, or internal hoops, distinguished by the letter E, fig. 2. These shelf pieces are composed of several lengths of timber scarfed or joined together by coaks, or circular dowels, so as to form a kind of internal hoop, extending from the hooks forward, to the transoms abaft, to the underside of which, as well as to the under parts of the beams, they are securely coaked, and being then firmly bolted to the side, instead of becoming a mere local fixture of the beam to the ship's exterior frame, as the knees formerly were, they afford a continued and general security. The shelf piece is also a tie to the top side in a fore and aft direction, co-operating with the trussed frame, as already explained.

Chocks.

(279.) The beams are also secured by chocks, represented in H, fig. 2, placed under all the shelf pieces in the wake of the beams, excepting the orlop, in such a manner as to receive the up and down arm of the iron knees. The lower ends of those under the gun deck shelf piece, step on the ends of the orlop beams, and those of the several decks above, step on the projecting part of the spirketing below. The chocks, particularly those between the orlop and gun decks, admit of their being driven into their respective places very tightly, thereby acting like pillars. Another advantage attending them, is their great tendency to stiffen the ship's side, and to prevent the beam ends from playing on the fastenings when the ship is rolling, or straining under a press of sail.

Iron knees.

(280.) The curved iron plate knees for securing the orlop beams, and the iron forked knees of the other decks, are described in figs. 2 and 3.

Improved decks.

(281.) In the old system of ship-building, the planks of the several decks acted only as mere platforms, or as a cover of a box unconnected with the sides, affording no strength to them whatever. In the new system of Seppings, however, they are so disposed, as not only to oppose an alteration of figure from a force acting on the ship in a lateral direction, but also are made subservient towards securing the beams to the ship's side. The framing and flat of the decks, excepting the quarter deck, forecastle, and round house, which are laid upon the old plan, are disposed as represented in fig. 5. The former, that is, the framing or ledges, and beams are denoted by ticked lines; the latter, or planks by black; those on the starboard side being laid contrarywise to the larboard. The midship ends of the diagonal planks abut against two strakes laid in a fore and aft direction outside the comings of the hatchways; the other ends approaching the timbers of the frame, the butts at each end being secured to a tier of carlings placed for that purpose. The flat or plank of the deck so disposed is connected with a certain number of coaks to the hooks, beams, and transoms. When the decks are thus laid, the waterways described in fig. 2, are brought on and coaked to the ends of the plank. These waterways being then bolted through the ship's sides, and also in an up and down direction, through the flat and shelf pieces, combine the whole in one homogeneous mass of strength.

In what part the weakness of a ship is commonly to be seen.

(282.) A run of three or four years' service most commonly discloses some examples of weakness in the fabric of a ship. These defects, among other places, show themselves at the beam ends, arising in a great degree from the local attachment of the beams to the ship's side, and the flat or covering being entirely unconnected. This imperfect fastening of the extreme ends of the beams, occasions them so to play and work upon the fastening, as often to cut the bolt holes into an oval form by the friction of the bolts. The usual remedy in such a state of things is to load her with additional materials, such as iron knees, standards, breast-hooks, &c.; thus adding greatly to the original weight of the fabric. It is evident that the first gale of wind the ship encounters, after being thus partially strengthened, must again reduce her to her former state of weakness.*

(283.) To remedy defects, whether arising from the decay of the materials, or from any other cause, the principles of Sir Robert Seppings, illustrated in fig. 1, cannot but hold out the most capital advantages; and in no particular is its superiority more manifest than in the decks; for by shifting them when worn too thin for calking, the original connection between the beams, the decks, and the sides will be restored as perfectly as at first.

Other improvements.

(284.) The tendency of the ship to stretch or draw asunder in her upper works, being by no means obviated by the short planks on the inside between the ports, Sir Robert substitutes a truss piece of plank in lieu of them, which being well secured at the abutments, materially aids the trussed frame, and gives great stiffness, thereby opposing any disposition to arch or hog aloft.

---

* It has hitherto been very generally believed, says Seppings, that stiffness or inflexibility in a ship is not strength, but that a yielding of the fabric is an essential quality to preserve it from being destroyed by the shocks it sustains. This erroneous opinion must have arisen from another equally incorrect, that a ship must be an elastic body, on account of the elasticity of the materials of which it is composed. It should, however, be remembered, that this elasticity of the materials must be very inconsiderable, since the small degree of elasticity in each piece must necessarily be neutralized in the fabric by the various directions of the parts of which it is composed. Hence a vessel, let her construction be what it may, whether loose or firm, cannot in any case be elastic. It follows also, that the action and reaction of the sea operating upon different parts of the fabric at different times, occasions, on account of the want of unity among the parts, a constant and increasing weakness, which by some may have been mistaken for elasticity.

When a sea strikes a ship forward, continues Seppings, the bow will rise with the sea; which passing aft, lifts the midships in succession, leaving the fore and aft parts with little or no support. Such shocks acting upon a body whose parts are not firmly connected, produce a bending and rebending of the fabric, the planks of the sides playing over each other, and the fastenings becoming strained and loosened by continued repetitions of the acting force. On the contrary, when a body is constructed with such general unity and fixedness of all its parts, that when one is moved the whole fabric must move with it, all the parts of the structure may be fairly said to bear their proper portion of the strain.

* This mode of strengthening ships, as Seppings truly observes, may be compared to that of a raft firmly secured in the first place by strong lashing, which after some time works loose, or rather by working is stretched. As it might be too tedious an operation to secure the raft by retightening the lashing, a small cord would be used for that purpose. It is clear whilst the small cord remains tight, no part of the strain can bear upon the strong but loose lashing, till the other stretches or breaks. So is it with a ship that has additional securities given her without refastening those which had worked or become strained.

Naval Architecture.

(285.) In fig. 4 the stern of a ship is represented with the trussing and iron work necessary for its security. By this the helm-port transom, which consumes one of the largest and most difficult trees required for a ship, is dispensed with.

Economy is combined with the views of Seppings.

(286.) It is a great principle in these views of Sir Robert Seppings, that not only strength, safety, and durability are so essentially promoted by them, but that economy holds also a capital and prominent place among them. At a time when reduction in our expenditure is so loudly called for, and the Royal Navy cannot be kept up without a large supply of foreign timber, it certainly adds to the credit of this accomplished Naval Architect, that, in a 74-gun ship, upwards of one hundred and eighty oak trees are saved by his masterly combinations, each tree having a load of fifty feet rough contents.

(287.) It must further, also, be borne in mind, that the consumption of large ship timber may be further diminished by the use of inferior and old ship timber, and if old ship timber were generally introduced, as in the case of the Ramillies, one-seventh part of the English oak required for a new 74-gun ship might be saved.

(288.) Another source of economy arises from the greater ease with which the lower part of the ship can be examined, in consequence of the omission of the inside planking. The ease, also, with which any part of the diagonal frame may be replaced, justifies the adoption of fir timber, particularly for the longitudinal pieces and trusses.

Reports made by distinguished officers in favour of these improvements.

(289.) We regret that our limits will not permit more than a brief allusion to the valuable Reports made on the Tremendous, the first ship to which Seppings's principles were applied, by the distinguished officers whose duty it was to make them. They were such as to stamp at once with the highest and best approbation his unrivalled combinations. Of this vessel, it was reported by Mr. Parkin, the master shipwright of Sheerness yard, that the sights on the gun-deck, at the distance of 163 feet, altered 0 in.; that those placed on the upper deck, at the same distance, changed but $0\frac{1}{4}$ in.; and those on the quarter deck and forecastle, at the same distance, altered but $0\frac{3}{4}$ in; after a more than three years' active service, exposed to perilous and turbulent storms. It was also remarked of the same ship, that "the orlop deck beams had not worked on the internal hoop, nor was the crust of the whitewash disturbed; the plates and bolts securing the diagonal riders and terminating under the internal hoop, as well as the heads of the riders, appeared as close as when fayed. The checks fore and aft, bolted under the gun-deck beams for receiving the forked knees, the breast hooks in the gunner's store room, as well as the bolts which fasten the forked knees, none had the slightest appearance of having worked. No appearance of the gun-deck beams having worked on the internal hoop which receives them was to be found; nor any leaks or dampness between the gun-deck water ways, the beams being so perfectly dry, as to have permitted, in many places, the cobwebs to collect between the timbers. The main and gun decks displayed no traces of working, and the same observation was made on the beams of the quarter deck and forecastle; and the whole ship throughout appeared in as perfect a state, as if she had been in dock upon the blocks."

Comparison of three first-rates.

(290.) In the instance, also, of three ships of 120 guns, the Nelson, the St. Vincent, and the Howe, whose forms and dimensions were precisely the same, and whose frames, beams, and external planking were of the same scantlings, it was remarked of the two former, built according to the old plan, and of the latter, built according to the new, that after the first of these vessels was launched, she altered nine inches and a half from her original sheer, and the St. Vincent nine inches and a quarter; but the Howe changed only three inches and five-eighths. The whole machine in the former ships, observes Seppings, was generally disturbed, but the Howe exhibited no such symptoms of weakness.

These useful and important plans objected to.

(291.) No invention or discovery is, however, destined to take its rank in the great catalogue of scientific truths without controversy and dispute; and, perhaps, on the whole, Knowledge is benefited by the furnace it has to pass through. To the inventor, or discoverer, it cannot but be a painful ordeal, but it is the tax he must pay for his celebrity. In the present case it was broadly insinuated that Seppings had borrowed his principles, whereas no application at all resembling his admirable plans can be found in any of the Continental writers on Naval Architecture. The propriety of a different disposition of the materials entering into the construction of a ship, has at different times been suggested by shipbuilders, and partial alterations have in consequence been introduced; but no one, so far as we can trace, has at any time proposed a system of diagonal trussed framing at all resembling that of the great ship-builder adverted to. "If I have received any assistance," he ingenuously observes, "in the progress of this new system, now universally adopted in the British Navy, it was from the plans and drawings of the celebrated bridge of Schaffhausen, and from no other source."

Candour of Sir Robert Seppings.

It was objected that the braces and trusses were applied the wrong way.

(292.) It may be proper, however, to advert to one objection of a practical kind advanced against the new system. It was asserted by some that the braces and trusses applied by Sir Robert Seppings, were disposed in directions precisely the reverse of that which they ought to have been. To meet this objection the following decisive experiment was appealed to.

Experiment with an old 74.

(293.) Early in the year 1817, the Justitia, an old Danish 74-gun ship, was ordered to be broken up on account of her defective state; and Seppings having observed her to be considerably arched or hogged, determined, notwithstanding her age and defective state, to apply the trussing principle to a certain extent, with a view to observe what effect it would produce on a fabric reduced to so weak and shaken a condition.

Description of it.

(294.) The officers of the yard were directed to place sights on the lower and upper gun-decks prior to her being taken into dock; and to ascertain, when she grounded on the blocks, how much she had altered from the state in which she was when afloat. They were then to place a certain number of trusses in the hold, some in the fore part of the vessel inclined forward at about an angle of 45°, and others in the after part of the vessel inclining aft at the same angle. Others were also to be placed at right angles to the former, so as to act against the beams of the deck. In the ports also, other trusses were introduced, those in the ports forward inclining forward in an angle of 40°, and those in the midships aft, at the same angles, but in an opposite direction. As it was uncertain where the centre of fracture would take place, a few of the port-

holes about the centre of the ship had trusses introduced into them in both directions. Wedges were applied to the heels of the trusses to set them tight. The ship being thus partially trussed, the water was let into the dock, and the ship floated out of it into the basin, where she was to lie one hour, when a Committee was to examine the sights, and ascertain how much the ship had altered; and again, what change had taken place in twenty-four hours after floating. This being done, the trusses were to be disengaged in as short a time as possible, in order to observe whether the effect of their removal would be instantaneous or gradual.

Report of the Committee appointed to examine the same.

(295) The following is an extract from the Report of the Committee:—

"When the ship was in dock, on blocks perfectly straight, she came down in the midships, by the sights placed in the gun-deck, two feet two inches and a half; and by those on the upper deck, two feet three inches and a quarter; and when undocked, with the trusses complete and in their places, she hogged, or broke her sheer, by the sights on the gun-deck, one foot two inches and five-eighths; and at the expiration of twenty-four hours she had hogged, or further broke her sheer, two inches and five-eighths, and then appeared stationary and completely borne by the trusses.

(296.) "We then proceeded to take away the trusses in the hold, and when they were wholly disengaged, she further hogged, or broke her sheer, six inches. We next proceeded to take away the trusses in the ports, and when they were wholly cleared, she dropped at the extremities, or further hogged, three inches and a half, and was in that position when tried twenty-four hours after.

(297.) "We further beg to state, that the whole of the trusses alluded to as placed at right angles to the first introduced, slackened as the ship floated from the blocks, and became short from half an inch to three inches and a half, and partook of no part of the pressure; which, in our opinion, clearly proves that the direction in which Sir Robert Seppings has applied his diagonal frame is correct, as also the great utility of the trussing system; for although the ship, from her very defective state, was much against so severe an experiment, it has proved to us its good effects most satisfactorily; for many of the trusses in the ports forced the timbers three-eighths of an inch within the ends of their covering planks, thereby lessening their effect from what it would have been if the ship had been of a sound texture; yet on a ship in this state, the trussing between the ports alone, after those in the hold were wholly disengaged, had the effect of sustaining the immense pressure of both ends of the ship in her worst position, and prevented her from breaking, which she would otherwise have done, from three to four inches, and which she actually and immediately did on their being disengaged."

(298.) This statement of the Portsmouth officers, says Sir Robert Seppings, will, I trust, be considered conclusive as to the benefits to be derived from the principle of trussing in the construction of ships; and although it was only applied from the keelson to the beams in the hold, and not to the ribs or frame of the ship, as is the case when ships are regularly built on this system, yet it sufficiently establishes the soundness of the principle.

(299.) When the Justitia first floated, continues Sir Robert, after being partially trussed, as described, the noise occasioned by the pressure on the trusses is stated to have been truly terrific, until she was fairly settled on them. The disengaging them also caused a similar crash.

Demonstration from abstract principles of the truth of the same.

(300.) A demonstration of the principle employed by Sir Robert Seppings may be seen in the XLIId Number of the *Journal of the Royal Institution*. If through the point in which the sustaining forces meet, a line be drawn to represent the measure and direction of the straining force, and on it a parallelogram be constructed, as a diagonal, having its sides parallel to the sustaining forces; then if the remaining diagonal of the parallelogram be drawn, and through the point where the sustaining forces meet, another line parallel to the same, all the parts of the framing on *the same side* of this line, as the straining force, will be in a state of *compression*, and all those on the other side of the same line in a state of *extension*. Applying this principle to fig. 7 and 8, plate iii., we shall deduce the results contained in the following Table.

	Nature of the Strain operating on the Timbers.				
	Braces.	Trusses.	Upper longitudinal piece.	Middle longitudinal piece.	Lower longitudinal piece.
With the braces in the fore body inclined aft, and those in the after body inclined forward as in fig. 7.	Extension.	Compression.	Extension.	Compression.	Compression.
With the braces in the fore body inclined forward, and those in the after body inclined aft, as in fig. 8.	Compression.	Extension.	Extension.	Extension.	Compression.

The primary object of the diagonal framing is to prevent arching; and if we suppose A F, in both figures, to represent the neutral line from which the arching proceeds towards both extremities, it is evident that it is the mechanical combination represented in fig. 7 which can alone prevent it. For since A, in that figure, by the hypothesis, is one of the neutral points of the system, it may be regarded as fixed; and the tendency of arching being to depress the points H, C and G, B, the effect on the braces A C and A B will be precisely similar to the weights applied in the preceding investigation; that is, to produce extension, and which is effectually provided for by the fastenings. The effect, moreover, brought at the same time into action by the trusses, in consequence of the disturbing force, is to resist, by the whole longitudinal strength of their fibres, all tendency to alteration of form; so that the effect exerted to depress the point C, is at once resisted by the fastenings appertaining to the brace A C, and to the longitudinal strength of the fibres of the truss proceeding from the unchangeable point F. The point E becoming, in this point of view, fixed, the action of the force which tends to depress the point H, in common with the point C, is resisted by the fastenings of the longitudinal timber A H, and by the longitudinal resistance of the fibres of the truss F H; so that, provided the fastenings of the braces and of the upper longitudinal timber are sufficient, and the abutments of the trusses and of the middle longitudinal timber are also proper, all tendency to arching will be resisted in proportion to the perfection of the materials, and the excellence of the workmanship.

(301.) But by referring to the converse disposition of the braces, as represented in fig. 8, it appears, from the preceding investigation, that the braces A C and A B are subject to compression. And since the point A is, by the hypothesis, the neutral or fixed point, the effect of the compression of the brace A C must be to depress the point C, and thus to promote the tendency to arching. Nor is this tendency to lower the point C prevented by the action of the truss F E; since the point F being fixed by the supposition, the tendency to extension which takes place in the truss must lower the point E, and thus promote the further declension of the point C. The point E being thus depressed, must add its effect to the extending force called into action in the truss E H, and thus produce a declension in the point H. Hence the whole effect of the disturbing force is to lower every part of the frame from C to H, and thus to promote the arching of the vessel. Hence the superiority of the present system of diagonal framing becomes apparent, and the advantages derived from it are demonstrated by the small alteration of form which ships now undergo in the act of launching.

More particular allusion to the causes of arching.

(302.) It is proper, however, to advert more particularly to some of the causes of arching, and in the first place to the condition of weight. There is a well-known and obvious inequality of the distribution of the weight and pressure, which, independently of all circumstances of construction, produce arching. It is possible, as Dr. Young observes, there may be cases in which a strain of a very different nature is produced, but in ships of war this tendency is universal. It is, however, very different in degree in the different parts of a ship; and of course, still more different according to the different modes of distribution of the ballast and stores occurring in different ships. In a modern 74-gun ship, fitted for sea, the length being 176 feet, and the breadth $47\frac{1}{2}$, the forces in ordinary cases are thus distributed:

Investigations of Dr. Young.

Distribution of forces.

(303.) Now although this general distribution of the forces may be supposed to exist, the laws of equilibrium will not allow us to suppose them to be concentrated in the middle of the respective portions, or equally distributed throughout them, still it is natural to suppose the excesses of weight and pressure to be arranged with as few abrupt changes as possible, in order that they may neutralize each other at the common termination of the adjoining portions, and to become more unequal in parts more remote from these neutral points. Thus the excess of weight in the first 49 feet being 72 tons, it may be supposed to begin at the rate of $\frac{144}{49}$ tons per foot, and to diminish gradually and equally, so that its centre of action will be at the distance $\frac{49}{3}$ from the end. The excess of pressure must increase in the next place, until, at the distance of 59 feet from the stern, it becomes $\frac{108}{10}$ per foot, and then diminish until it vanishes at 69, where the excess of weight must begin to prevail, becoming at 94, $\frac{118}{25}$ per foot, and vanishing at 119. The excess of pressure might then be supposed to increase gradually through the next portion, in order to avoid an abrupt change at its extremity; but this supposition would still be insufficient, and it becomes necessary to imagine that for 6.6 feet the forces remain neutralized, and the pressure then prevails, so that its excess becomes at last $\frac{119}{6.7} = 17.7$ per foot. It must then decrease for 17.5 feet, and the excess of weight at the extremity must become 19.7 feet, the neutral point being at 156.5. The equilibrium of the forces will then be expressed by the equation

$$72 \times 16.3 - 108 \times 59 + 118 \times 94 - 119 \times 134.5 - 155 \times 144.8 + 192 \times 169.5 = 0,$$

which Dr. Young imagines is sufficiently accurate for every purpose.

Determination of the strain for each point.

(304.) From this distribution of the forces, we obtain a determination of the strain for each point of the respective portions, which is in the joint ratio of the magnitudes and distances of all the forces concerned, on either side of the point, reduced into a common result. For the first portion it is

$$\frac{72}{49}x^2 - \frac{1}{6} \cdot \frac{144}{49} \cdot \frac{x^3}{49},$$

x being the distance from the stern.

For the second,

$$72\,(x-16\tfrac{1}{3})-\frac{1}{6}\cdot\frac{108}{10}\cdot\frac{(x-49)^3}{10}.$$

For the third,

$$72\,(x-16\tfrac{1}{3})-54\,(x-55\tfrac{2}{3})-\frac{108}{20}\,(x-59)^2+\frac{1}{6}\cdot\frac{108}{100}\cdot(x-59)^3.$$

For the fourth,

$$72\,(x-16\tfrac{1}{3})-108\,(x-59)+\frac{1}{6}\cdot\frac{118}{25}\cdot\frac{(x-69)^3}{25}.$$

For the fifth,

$$72\,(r-16\tfrac{1}{3})-108\,(x-59)+59\,(x-94)+\frac{118}{50}\,(x-94)^2-\frac{1}{6}\cdot\frac{118}{25}\cdot\frac{(r-94)^3}{25}.$$

For the sixth, from 119 to 125.6,

$$72\,(r-16\tfrac{1}{3})-108\,(x-59)+118\,(x-94).$$

For the seventh,

$$72\,(x-16\tfrac{1}{3})-108\,(x-59)+118\,(x-94)-\frac{1}{6}\cdot\frac{119}{13.4}\cdot\frac{(x-125.6)^3}{13.4};$$

and in the last 37 feet, the strain will be expressed by

$$(176-x)\,19.7\times\tfrac{1}{2}(176-x)-\frac{1}{6}\cdot 19.7\,\frac{(176-x)^3}{19.5}.$$

Hence we find the strain, at seven points, 22 feet distant from each other and from the ends, 605, 1993, 2815, 2244, 2655, 4610, and 1875; and by taking the differential of x in the seventh portion, we determine he maximum at $141\tfrac{1}{3}$ feet, amounting to 5261 tons, supposed to act at the distance of one foot.

Curve produced by such a strain.

(305.) In order to form an idea of the curve which would be produced by such a strain, acting on a uniformly flexible substance, we may consider the curvature as represented by the second fluxion of the ordinate y; and by finding and correcting the fluent separately for each portion, we may obtain the ordinate, or fall, at any given point corresponding to a given extent of arching of the whole fabric. It will, however, be sufficiently accurate for this purpose, to consider the forces as concentrated in a limited number of points, dividing those which act in the extreme portions into two parts, in order that the curvature may be continued to the ends; so that the whole of the forces may be thus distributed.

	Distances.	Forces.
At	0	+ 36
	$32\tfrac{2}{3}$	+ 36
	59	− 108
	94	+ 118
	134.5	− 119
	144.8	− 155
	163	+ 96
	176	+ 96

The strain for each portion may then be represented by $a - bx$, whence

$$\ddot{y} = a x \dot{x} - b x x \dot{x},$$

$$\dot{y} = a x \dot{x} - \frac{1}{2} b x^2 \dot{x} + c \dot{x},$$

and $$y = \frac{1}{2} a x^2 - \frac{1}{6} b x^3 + c x + d.$$

Dr. Young remarks it will be most convenient, in calculation, to make x begin anew with each portion, setting out from the middle, and to divide the numbers by 100, in order to shorten the operations. Thus, for the middle portion, from 88 to 59, the strain will be $.2028 + .36\,x$, a being $.2028$, and $b = -.36$; and when x becomes $.22$, y is $.00552$; and when $x = .29$, $\frac{\dot{y}}{\dot{x}} = .0740$, and $y = .0011$; which values being substituted in the equations for the next portion, we have $c = .074$, and $d = .0011$. By going through the whole length in this manner, we find the fall at the extremes, and at seven equidistant intermediate points, to be,

.08697
.05325
.02514
.00552
.00000
.00507
.02531
.06705
.12325.

If we wish to find the point at which the curve is parallel to the chord of the whole, we must inquire where $c = (.12325 - .08697) : 1.76$, which will be at 98 feet, or 10 feet before the midships.

Effects of pressure in a longitudinal direction

(306.) To the strain which the circumstances of weight and upward pressure produces, another must be added resulting from a cause, which, although not very inconsiderable, appears to have been altogether neglected before Dr. Young inquired into it; and this is, that partial pressure of the water in a longitudinal direction, affecting the lower parts of the ship only, and tending to compress and shorten the keel, while it has no immediate action on the upper decks. The pressure thus applied, must obviously occasion a curvature, if the angles made with the decks by the timbers are supposed to remain unaltered, while the keel is shortened in the same manner as any soft and thick substance, pressed at one edge between the fingers, will become concave at the part compressed. This strain, upon the most probable supposition respecting the comparative strength of the upper and lower parts of the ship, must amount to more than one-third as much as the mean value of the former, being equivalent to the effect of a weight of about 1000 tons, acting on a lever of one foot in length, while the strain, arising from the unequal distribution of the weight and displacement, amounts where it is greatest, that is, about 37 feet from the head, to 5260; and although the strain is considerably less than this exactly in the middle, and throughout the aftermost half of the length, it is no where converted into a tendency to "sag," or to become concave. It must, however, be remembered, that when arching actually takes place from the operation of these forces, it depends upon the comparative strength of the different parts of the ship and their fastenings, whether the curvature shall vary more or less from the form, which

results from the supposition of a uniform resistance throughout the length.

(307.) Our limits will not permit us to pursue the analytical conditions connected with this longitudinal pressure; and we can, therefore, only add that these different causes of arching being independent of each other in their operation, their effects will be simply united into a common result. Hence the whole curvature of the ship, supposing its strength equable throughout its length, may be thus represented.

Naval Architecture.

Force of the wind and waves.

(308.) Important as are the effects produced on the framework of the hull, when it floats quiescently on the water, their amount is greatly increased when it is exposed to the forces of the wind and waves. The effect of the wind, Dr. Young observes, is generally compensated by a change of the situation of the actual water line, so that its amount may be estimated from the temporary or permanent inclination of the ship; and the force of the waves may be more directly calculated from their height and breadth. As a fair specimen of the greatest strain likely to arise from the waves in any common circumstances, we may consider the case of a series of waves 20 feet in height, and 70 in breadth, their form being such, that the curvature of surface may be nearly proportional to the elevation or depression.

How strains arising from waves may be computed.

The strain produced by the pressure of waves of given magnitude, may be calculated from the comparison of the displacement with respect to their surface, with the displacement with respect to a level surface. It is hence found that the greatest strain takes place in a 74-gun ship, at the distance of about 18 feet from the midships, amounting to about 10,000 tons, at the instant when the ship is in a horizontal position, while, in more common cases, when the waves are narrower, the strain will be proportionally smaller and nearer to the extremity. Hence it appears, that the strain produced by the action of the waves may very considerably exceed in magnitude the more permanent forces derived from the ordinary distribution of the weight and pressure; so that when both strains cooperate, their sum may be equivalent to about 15,000 tons acting on a lever of one foot, and their difference, in opposite circumstances, to about 5000. There may, Dr. Young further observes, possibly be cases in which the pressure of the waves produces a still greater effect than this; and it may also be observed, that the agitation accompanying it tends to make the fastenings give way much more readily than they would do if an equal force were applied less abruptly. At the same time, it is not probable that this strain ever becomes so great, as to make the former perfectly inconsiderable in comparison with it, especially if we take into account the uninterrupted continuance of its action: it appears, therefore, to be highly proper that the provision made for counteracting the causes of arching should be greater than for obviating the strain in the contrary direction; for example, that if the pieces of timber intended for opposing them were, on account of the nature of their fastenings, or for any other reason, more capable of resisting compression than extension, they should be so placed as to act as shores rather than as ties; although it by no means follows, from the form which the ship assumes after once breaking, that the injury has been occasioned in the first instance by the immediate causes of arching; since, when the fastenings have been loosened by a force of any kind, the ship will naturally give way to the more permanent pressure which continues to act on her in the state of weakness they superinduced.

Breaking transversely.

(309.) The pressure of the water against the sides of a ship has also a tendency to produce a curvature in a transverse direction. This is, moreover, greatly increased by the distribution of the weight, the parts near the sides being the heaviest, while the greatest vertical pressure of the water is in the neighbourhood of the keel. This pressure is often transmitted by the stanchions to the beams, so that they are forced upwards in the middle; when they are unsupported, the beams are more generally depressed in the middle, by the weight of the load which they sustain; while the inequality of the pressure of the water cooperates with other causes in promoting the separation of the sides of the ship from the beams of the upper decks. On the other hand, Dr. Young observes, the weight of the main mast often prevails partially over that of the sides, so that the keel is forced rather downwards than upwards in the immediate neighbourhood of the midships. The tendency to a transverse curvature is observable, when a ship rests on her side, in the opening of the joints of the planks aloft, and in their becoming tighter below; although this effect depends less immediately on the absolute extension and compression of the neighbouring parts, than on the alteration of the curvature of the timbers in consequence of the pressure.

Lateral curvature.

(310.) Under such circumstances, there is, moreover, a tendency to produce a lateral curvature, and shores are sometimes employed to prevent its effects, when a ship is "hove down" on her side. This, indeed, is comparatively a rare occurrence; but when large waves strike a ship obliquely, they must often act in this manner with immense force. The elevation on one side may be precisely opposite to the depression on the other, and the strain from this cause can scarcely be less than the vertical strain already calculated. Its effects, however, are less commonly observed, because we have not the same means of ascertaining the weakness which results from it, by the operation of a permanent cause. When a ship possesses a certain degree of flexibility, she may in some measure elude the violence of this force by giving way a little for the short interval occupied by the passage of the wave; but her sailing in a rough sea must be impaired by such a temporary change of form.

Investigations of Dupin on arching.

(311.) Dupin, in a Paper in the *Philosophical Transactions* for 1817, has investigated the analytical conditions of arching. By representing by x the distance of any part of a vessel from a vertical plane, and

Naval Architecture.

by dx the thickness of the infinitely small sections parallel thereto, $\phi(x)\,dx$ denoting the weights of those sections, and $\psi(x)\,dx$ that of the water which they respectively displace, the integral of the total moment of the forces will be

$$\int\{x\phi(x)\,dx - x\psi(x)\,dx\}.$$

Now, in order that this function may be either a maximum or a minimum, its variation must be zero, and hence we have

$$\delta\int\{x\phi(x)\,dx - x\psi(x)\,dx\} = 0.$$

In this latter expression, however, neither of the original sections alters its weight; and the functions $\phi(x)$ and $\psi(x)$ remain constant, as well as the thickness dx of the sections, only by removing the plane, with respect to which the moments are taken, to the distance δx, the section of which $\phi(\delta x)$ represents the weight, and $\psi(\delta x)$ its displacement. Hence we have

$$0 = \delta\int\{\phi(x) - \psi(x)\}\,x\,dx$$
$$= \int\{\tfrac{1}{2}[\phi(\delta x) - \psi(d x)] + [\phi(x) - \psi(x)]\}\,dx\,.\,\delta x.$$

But since the functions $\phi(x)$ and $\psi(x)$ become zero, when we cause x to vanish, these expressions represent the weight and displacement of a vanishing section; and hence we see that $\phi(\delta x) - \psi(\delta x)$ becomes infinitely small when compared with $\phi(x) - \psi(x)$.

If, therefore, the expression $\phi(\delta x) - \psi(\delta x)$ may be neglected, much more may the function

$$\tfrac{1}{2}[\phi(\delta x) - \psi(\delta x)]\,dx\,.\,\delta x;$$

and hence the general expression representing the condition of either the maximum or minimum of the moments tending to produce arching will be

$$0 = \delta x\int\{\phi(x) - \psi(x)\}\,dx,$$

where $\int\phi(x)\,dx$ is the total weight of the sections under consideration, and $\int\psi(x)\,dx$ the total weight of the displacement of the same sections.

(312.) Hence we learn, that the sum of the moments tending to produce arching, is either a maximum or a minimum, when the weight of the part of the vessel, either before or behind the plane of the moments, is equal to the weight of the water displaced by the same part of the ship.

(313.) The maximum condition may be distinguished from that of the minimum, according as the term of the formula neglected has the *same* or a *contrary* sign from the function of the total moment

$$\int\{\phi(x) - \psi(x)\}\,x\,.\,dx,$$

and the sum of the moments, with relation to the plane determined, will be a *minimum* or a *maximum*.

Since, however, $\phi(\delta x)\,\delta x$ is the weight of the section having δx for its thickness, and $\psi(\delta x)\,\delta x$ the weight of the water displaced by the same section, the function

$$\tfrac{1}{2}[\phi(\delta x) - \psi(\delta x)]\,\delta x\,.\,dx$$

will be positive or negative, according as the weight of the infinitely small section commencing at the plane of the moments, is greater or less than the weight of the water displaced by the section itself. Hence Dupin deduced the following general theorems.

General theorems.

I. *That when a vertical plane divides a vessel into two parts, so that the weight of each part is equal to the weight of water displaced by it, the moments of those parts estimated in relation to the same plane, to produce what we have denominated arching, will be either a maximum or a minimum.*

II. *That this effect will be a maximum, when the infinitely small section contiguous to the plane of the moments, has its own moment in a contrary direction to that of the total moment.*

III. *That the effect will be a minimum when this section has its own moment acting in the same direction as the total moment.*

Applications of these theorems to Dr. Young's forces.

(314.) In order to apply these theorems to the system of forces adopted by Dr. Young as representing the conditions of the 74-gun ship before alluded to, Dupin assumed a line A O, fig. 9, coincident with the water's surface, and in it certain segments, A C, C E, E G, G H, H K, K M, and M O, corresponding to the quantities in the first of the following columns. On certain of these segments he supposed triangular areas to be formed equivalent to the differences between the weights of the sections and their displacements as estimated by Dr. Young. For instance, on the segment A C he formed the right-angled triangle A B C = + 72, below the water line, because the weight exceeded the pressure. On C E, also, he reared the isosceles triangle C D E = − 108, and above the same line, because the pressure in this case exceeded the weight. On E G, likewise, he formed a triangle, E F G = + 118; on H K the right-angled triangle, H I K = − 119; and lastly on K M, M O the right-angled triangles I K M, M O N, the former having an area of − 155, and the latter of + 192, the difference being + 37.

Values of the Segments making up the total Length of A O of the Ship.	Areas equivalent to the Differences between the Weights of the Sections and their Displacements.
A C = 49	Surface A B C = + 72
C E = 20	Surface C D E = − 108
E G = 50	Surface E F G = + 118
G H = 6.6	
H K = 13.4	Surface H I K = − 119
K M = 17.5	Surface I K M = − 155
M O = 19.5	Surface M N O = + 192
Total A O = 176	Total = 000

(315.) Now, after determining the centres of gravity of the several triangular areas here referred to, and letting fall perpendiculars from them on the primitive line A O, he obtained an equation of equilibrium identical with that given by Dr. Young. On this equation Dupin makes many judicious observations. In the first place, he remarks, that the triangle E F G ought not to be regarded as isosceles, since its vertex is the point in which the difference between the weight of the section and its displacement, is the greatest in this part of the vessel, and which ought to correspond with the position of the main mast. But the main mast is situated abaft the middle point ⊕ of the vessel, and is, therefore, nearer the common point of origin A by 19 feet $\left(=\frac{176}{2} - 69\right)$ than the central part of the ship. The learned Frenchman thinks the vertex of the triangle C D E to be too far forward by at least 13 feet. To make the sum of the moments vanish also, Dr. Young was obliged to transfer a weight of 37 tons from the fore part of the ship to its displacement.

Naval Architecture.

Correction of the hypothesis of Dr. Young.

(316.) To correct the hypothesis of Dr. Young, and apply the theorems just investigated to the maximum and minimum sections, Dupin drew within the triangle C D E a line P p, so as to cut off from it the negative area C D P p, numerically equal to the area of the triangle A B C. Since, therefore, the area of the trapezium C D P p is by this supposition $= -72$, it follows that the area of P p E $= -36$; and similar triangles being to each other in the duplicate ratio of their homologous sides, we have

$$\Delta D d E : \Delta P p E :: d E^2 : p E^2,$$

or $$-54 : -36 :: 10^2 : \frac{-36 \times 10^2}{-54}.$$

Hence

$$p E = 20 \sqrt{\frac{1}{6}} = 8.15;$$

and, consequently,

$$A p = A E - p E = 60.85.$$

If we now take the moments of the triangle A B C, and the trapezium C D P p = Δ C D E $-$ Δ P p E, with respect to the line P p, in which case we shall have for the positions of the centres of gravity

$$p b = A p - A b = 60.85 - 16.3 = 44.55,$$
$$p d = d E - p E = 10 - 8.15 = 1.85,$$
and $$\frac{1}{3} p E = \frac{8.15}{3} = 2.72;$$

and hence for the moments required the following results:

$$44.55 \times +72 = +3207.6$$
$$1.85 \times -108 = \quad -199.8$$
$$2.72 \times -36 = \quad -97.8,$$

which gives for the final moment the positive quantity 2910, indicating the tendency by which the stern of the vessel falls.

(317.) If, however, in conformity to the second theorem, we find that the moment of the infinitely small section contiguous to the plane of the moments here referred to, be of a contrary character to that of the definitive moment just deduced, we shall be justified in concluding that the moment 2910 is absolutely the greatest that can be discovered; and that the moment of the infinitely small section alluded to is *negative* is apparent, on account of its partaking of the general condition of the triangle C D E, which has all its sections of a *less* weight than the volumes of water they respectively displace, whereas the total moment by the preceding calculation is clearly *positive*.

(318.) Let us now consider the conditions of the sections comprised between the points E and G; and since the area of the triangle E F G is by the hypothesis greater than the area of the triangle E p P, let us suppose a line Q g to be drawn at right angles to the water's surface, so as to cut off the triangle Q g E equal to the triangle E p P. To fix the position of this line, we have, by means of the similar triangles F f E, Q g E, the following proportion:

$$\Delta F f E : \Delta A g E :: E f^2 : E g^2,$$

or $$59 : 36 :: 25^2 : \frac{36 \times 25^2}{59}$$

Hence

$$E g = 150 \sqrt{\frac{1}{59}} = 19.5,$$

and, consequently,

$$A g = A E + E g = 88.5.$$

(319.) In order to estimate the moments of the triangles A B C, C D E, Q g E, with regard to the line Q g, we shall have for the positions of the centres of gravity,

$$g b = A g - A b = 88.5 - 16.3 = 72.2$$
$$d g = A g - A d = 88.5 - 59 = 29.5$$
$$\frac{1}{3} E g = \frac{19.5}{3} = 6.5,$$

and for the moments required,

$$72.2 \times +72 = +5196$$
$$29.5 \times -108 = \quad -3186$$
$$6.5 \times +36 = +234,$$

giving for the final moment the positive quantity 2244.

(320.) If now we consider the nature of the sections which are infinitely near Q g, it will be perceived that their weights exceed their displacements, and that their tendency, hence, is to produce a degree of curvature in the ship analogous to the moment just determined. Hence the moments tending to arch the ship longitudinally in Q g, at the distance of 88.5 feet aft, must by the theorem be a *minimum*.

(321.) In the next place, let us consider the nature of the sections situated between the points H and M. The displacement of these sections exceed their absolute weights by a quantity equivalent to $+155 - 119$, this amount being greater than the total result

$$+72 - 108 + 118.$$

Hence it is evident that we must cut off from the triangle H I M, by means of a vertical line R r, such a triangle H R r as may make

$$A B C + E F G - G D E - H R r = 0,$$

and which condition furnishes for the value of the area of the triangle sought

$$H R r = A B C + E F G - C D E$$
$$= 72 + 118 - 108$$
$$= 82.$$

Hence

$$\Delta H I K : \Delta H R r :: H K^2 : H r^2,$$

or

$$119 : 82 :: 13.4^2 : \frac{82 \times 13.4^2}{119}.$$

Whence

$$H r = 13.4 \sqrt{\frac{82}{119}} = 11.21,$$

and $$A r = A H + H r = 125.6 + 11.21$$
$$= 136.81.$$

(322.) To obtain the moments of the triangles A B C, C D E, E F G, and H r R with regard to the line R r, we shall obtain for the positions of the centres of gravity

$$r b = r A - A b = 136.81 - 16.3 = 120.51$$
$$r d = r A - A d = 136.81 - 59 = 77.81$$
$$r f = r A - A f = 136.81 - 94 = 42.81$$
$$\frac{1}{3} r H = \frac{11.21}{3} = 3.74;$$

and hence for the moments themselves

$$
\begin{array}{lll}
120.51 \times +\ 72 = + 8676.72 & & \\
77.81 \times -\ 108 = & & -\ 8403.48 \\
42.81 \times +\ 118 = + 5051.58 & & \\
3.74 \times -\ 82 = & & -\ 306.68
\end{array}
$$

giving for the definitive moment, the positive number 5018.14.

(323.) Thus the sections infinitely near to R r, will have their weights less than the resistance of the water they displace, the moments of the same sections acting in a contrary direction to that of the total moment. Hence, by the second theorem, the moment just deduced is a *maximum*.

(324.) At the extremities of the vessel, the sum of the moments being zero, must furnish likewise two minimum values. Hence the *maximum* and *minimum* values of the moments tending to arch the vessel are those in the following Table :

Naval Architecture.

At zero, or the point A.	At A p = 60.85 feet from A.	At A q = 88.53 feet from A.	At A r = 136.81 feet from A.	At A o = 176 feet from A.
Minimum.	Maximum.	Minimum.	Maximum.	Minimum.
Value of the moment = 0.	Value of the moment = 2910.	Value of the moment = 2244.	Value of the moment = 5018.44.	Value of the moment = 0.

(325.) If we refer to the *maximum* and *minimum* sections passing through A p and A q, we perceive that from the former to the latter there must be a continual declension in the value of each moment; and that, consequently, at 88 feet from the origin at A, the magnitude of the moment must be greater than at the distance of 88.53 feet from the same point where the minimum section exists; a conclusion, it may be remarked, agreeing with the theory of Dr. Young. So, also, by referring to the *maximum* sections deduced by Dupin we shall find them greater than the sections nearest to them in the investigation of Dr. Young.

(326.) Similar analogies, however, do not exist, when we compare the *maximum* section of Young with the deductions of Dupin. The former makes that section to exist at the distance of 141.3 feet from the after part of the water line, producing a strain equivalent to 5261 tons acting at the distance of a foot; whereas the latter estimates the strain at a like point at 4920.3 tons. These investigations are far, however, from being perfect. Observation joined to future applications of analysis will be necessary to render it perfect.

(327.) It has been very ingeniously observed, says Dr. Young, that arching is not only a part of the evil occasioned by a ship's weakness, but that it has an immediate tendency to afford a partial remedy for the cause which produces it, by making the displacement greater at the extremities of the vessel, and smaller in the middle; but, in fact, this change appears to be too inconsiderable in its extent, to produce any material benefit, the strain at the midships being diminished by each inch of arching only 66 tons, supposed to act at one foot; so that very little relief is obtained from the change, in comparison with the whole strain.

Chapman's views of arching.

(328.) What the views of Chapman were respecting the trussing of ships may be gathered from the following extract from his Work on ships of war, and by which it will be seen how much superior the views of Seppings were to those of the Swedish ship-builder.

(329.) If a ship were cut transversely into numerous parts, and each part were enclosed at its ends, so as to be water tight, those parts nearest the extremities of the ship would sink much deeper, and the middle parts rise higher out of the water, and thus assume a different form from that shown in the drawing, namely, higher in midships and lower at the extremities. And as the form of a ship above or below the water cannot be otherwise than it is now, and always has been, nor can the situation of the weights by which the ship is pressed down be altered, this defect can be obviated in another manner than by a certain security through the whole length of the ship, not, however, wholly, but, in a greater or less degree, depending on using the best means, and those which cause the least inconvenience.

(330.) In the year 1759 two vessels were built at Stralsund, to be used in the Frische-haf, in a War with the King of Prussia, the one about 100 feet long, and above 20 feet in breadth, and drawing not more water than $7\frac{1}{2}$ feet: the other about 80 feet in length, and drawing $5\frac{1}{2}$ feet water. They carried heavy armaments, especially at the extremities, and were made to row as well as sail; and on account of this armament and many considerable weights, a strong combination of the fabric was necessary; but although their bottoms had the greatest fulness which could be reasonably allowed to them, they could not thereby obtain a sufficient displacement. It was therefore necessary to build them with timbers of as small scantling as possible; and as on this account they could not possess the necessary strength, especially in regard to their arching, the following method was adopted.

(331.) Parallel to the middle line of the vessels on each side, about half way between the keelson and the orlop clamps, a strake of oak was laid on its edge six inches thick, along the whole length of the hold, let down an inch over all the timbers, the ends of which extended to the deck, both forward and abaft, which was called the builge-strake, and which was fastened with bolts through the timbers and outside plank. Under the beams of the deck, perpendicularly over the builge-strake, was fixed on its edge a strake of fir along the whole length of the vessel six inches thick, with a score one inch deep for the beams, to which it was bolted, and was called the longitudinal shelf. Both ends of this shelf lay against the timbers of the frame, and its lower side on the builge-strake, to which it was coaked, both forward and abaft, and was fastened with bolts through the builge-strake, timbers, and outside

plank. Between the builge-strake and the shelf, vertical oak pillars were placed, at a distance from each other equal to their length; from the lower end of one pillar to the upper end of each following pillar was placed a diagonal shore of fir. See more on this subject in the *Architectura Navalis Mercatoria*, printed at Stockholm in the year 1768, and in the Treatise on Ship-building relating to it, printed at Stockholm in the year 1775, p. 217; and as it was found that the object was obtained by the use of this diagonal trussing, all armed vessels, as well great as small, have had trussing in all respects similar to it.

(332.) In the year 1772 an armed vessel was built at Stockholm about the same size as that first named, but instead of the vertical pillars being of oak, as in the former vessel, they were of fir, but in all other respects as before. Immediately the vessel was off the slip it was found that it had straightened in the launching four inches, but within twenty-four hours it recovered so much of its former sheer, that the sheer was straightened by only two inches. When it was examined in what manner this had taken place, it was found that the abutments of the shelf had pressed into the vertical fir pillars, nearly half an inch in some and it was this yielding of the timber, which in some, degree recovered itself, by which the arching was diminished. On the lower ends of the pillars against the wedges little or no indentation was observed. The sliding plank on which the builge-ways ran, during the launching, did not extend to the edge of the water, but terminated about a foot above it, so that when the middle of the vessel was at the end of the sliding plank, its foremost end had not the support of the water, and became balanced; and it was just at this moment that the arching must have taken place.

(333.) About the year 1789 two larger vessels were built, each carrying one tier of 36-pounders, but without any diagonal trussing. They were used in the Russian war, and became much arched, and when they afterwards required a large repair, it was found that the keel, which was 135 feet in length, had curved upwards in midships $2\frac{1}{4}$ feet, on which account the usual diagonal trussing in the hold was given to them.

(334.) Suppose it be required, says Chapman, to make a similar disposition of security for a ship of the line, for instance, a ship of 110 guns, and let fig. 10 and 11 represent this arrangement. As this strengthening should be applied at the place most convenient in respect to the stowage of the hold, it is most important to obtain a sufficient breadth for a certain number of water-casks, here considered to be four whole and one half cask on each side the keelson or midship pillars. If five whole casks were taken, the trussing would come too far out into the builge. The nearer it comes, also, to the middle of the ship the greater effect it has in preventing arching; therefore, when the diameters of four whole and one half cask are added together, with half the thickness of the midship pillar, and the whole thickness of the diagonal shores, it gives $18\frac{3}{4}$ feet, which is the distance of the middle line of the ship from the outside of the diagonal shores. To show this trussing, the ship's side, from one end to the other, as far as this trussing extends, is supposed to be laid open. *a* is the frame timbers, *b* the ceiling, *c* the riders, *d* the builge-strake, *e* the fillings between the riders, builge-strake, and ceiling, *f* the shelf under the beams, which being two thicknesses in breadth, are bolted together to give shift to each other. Over these are laid three strakes of deck plank of such a thickness that they can be let down one inch over the beams, with bolts through these beams and the shelf. *g* is the vertical pillar, and *h* the diagonal or shore. In other respects the disposition of the pillars and trusses, &c. is as already described.

(335.) It must be further remarked, that all the parts which belong to this trussing, and terminate at the extremities of the ship, are there secured in the best manner to the ship: therefore not only must the ends of the builge-strake and shelf be coaked together at the extremities of the ship, but also the security there required is supplied by fillings lying longitudinally, which are not only coaked together but also to the builge-strake and shelf; and which extend as far as where the shelf and builge-strake are about 2 or $2\frac{1}{2}$ feet apart, by which the whole mass, namely, the shelf, filling, builge-strake, timbers, and outer plank, receive a sufficient number of bolts, which are driven from without and within, as *xx*. Likewise the fillings *e* under the builge-strake and between the riders are coaked to the ceiling, and the builge-strake to the fillings *e*. The combination of this disposition of trussing at both extremities of the ship cannot always, however, be performed in the same manner. For example, if the trussing comes nearer to, or further from, the middle line of the ship, or if the ship has greater or less fulness at the extremities, &c., each of these cases requires a different method, the circumstance of the part to be strengthened determining the manner of performing it.

(336.) This method of security, when it is well executed, will certainly accomplish the object. That the preventing arching is of consequence may be inferred hence. When a coasting vessel, which was to carry a considerable armament, and more than 100 feet long, was strengthened in this manner, the day before it was launched, the wedges at the lower ends of the pillars were for the last time driven up. When all the wedges at the pillars fore and aft on both sides were hardened up at the same time, the upper end of the keel rose so much from the upper block, that the block became loosened and movable. It should also be remarked, that this vessel was not deep in the hold, had only one deck, with light upper works and small scantlings.

(337.) As the timber and iron work required for this trussing would be equal to the weight of 1200 cubic feet of water, the three-decker would sink about $1\frac{1}{2}$ inch deeper in the water, by which the height of the battery would be so much the less; but as this should not be allowed, the drawing should be altered, so that the displacement, which is $=152{,}875$, may become $=154{,}075$ cubic feet. This alteration can be made as follows:

(338.) To keep the ⊕ section and all the other sections at the same places as before, the exponent n of the line of sections remains the same $= 2.6385$, whence the area of the ⊕ section is $= \dfrac{n+1.D}{n\,l} = 1027.20$. Let h be a tenth of an inch longer, then h is $= 18.213$, hence B is $= 56.4$; the breadth has thus obtained an increase of 0.13 foot.

(339.) The lowering of the metacentre, which is caused by the increase of the displacement, is counterbalanced by the small increase of the breadth; thus the situation of the metacentre is not changed. This brief account of the notions of the celebrated Chap-

man, shows at once the superiority of the plans of Seppings.

On the Heads and Sterns of Vessels.

Heads and sterns of vessels.

(340.) In the earliest times, the favourite emblem of each particular nation rarely failed to appear when any opportunity presented itself for its introduction. Accordingly we find the Owl constantly appeared on the Athenian prow, and the Cock, the emblem of vigilance, on those of the Phœnician Colonies; and that much importance was attached to the formation and decoration of this part of a vessel, may be gathered from the abundant illustrations afforded by ancient coins. Many of the designs remaining to us of these ancient prows, prove their contrivers to have been anxious, not only for the employment of such improvements and inventions as had mere utility, or the annoyance of enemies to recommend them, but many were designed for no other purpose than magnificence and splendour.

Decorations of stern surpassed those of the head.

(341.) The decorations of the stern, or poop, however, very much surpassed those of the head; and to it were attached, at the extremity of a staff or upright pole, those floating streamers of various colours, which have descended even to our present times. The cumbrous and expensive ornaments, therefore, which continued to decorate ships at the commencement of the XVIIIth Century, may find an apology in the customs that prevailed two thousand years ago.

Change in the figure-head of our ships in 1796.

(342.) In 1796, the Admiralty, at the head of which was Earl Spencer, directed that the ponderous heads which disfigured our ships should no longer be continued, and that the galleries and carved work should be removed from their sterns. This was a great step towards that simplicity so much to be desired in every mechanical construction; but it was not till 1811, that Seppings was enabled to bring the simple circular bow now employed into use; nor till 1816 that he proposed that the same system should be adopted in the stern.

Seppings's bow and stern.

(343.) The alteration of the bow was generally regarded as a salutary improvement; but the change of the stern met with the most violent opposition, founded chiefly on the erroneous idea that our seamen were likely to run from the enemy. Other notions connected with beauty and deformity were urged with singular pertinacity; but the unanswerable arguments founded on experimental evidence, satisfactorily proved to every unprejudiced mind, that the introduction of this change of form, added considerably to the strength of the ship, considered as a mechanical framework; that the safety of the crew was very much increased both from the effects of a sea striking the stern, and from shot fired by an enemy; and, moreover, that the additional means afforded for attack and defence were very much increased.

Comparison of means of attack by round and square sterns.

Some evidence of the mechanical strength may be gathered from a simple comparison of the forms in fig. 12 and 13; and of the augmented means of attack or defence from fig. 14 and 15. The objections made as to form have been entirely obviated by the model proposed by Mr. Roberts; and it is satisfactory to find, that an improvement, too long regarded with indifference or hostility, is now likely to be adopted as a permanent improvement in the British Navy.

On Timber for the Navy.

Timber for the Navy.

(344.) When we survey the framework only of a single ship of war, the thought immediately occurs to the mind how many acres of forest trees must have been felled in order to furnish suitable timber for its formation; and when we further reflect on the slow growth of the oak, and on the comparatively limited surface of territory in our own Country covered by this noble tree, together with the enormous consumption necessary for the formation and maintenance of our Navy, and all the hosts of our commercial fleets, with all the varied requirements of the useful Arts, it cannot but become an anxious subject for consideration, how these multiplied demands can in perpetuity be supplied.

Importance of cultivating timber pointed out by Evelyn.

(345.) The public attention was first aroused to the importance of cultivating timber, by the immortal *Sylva* of Evelyn. "Many causes," says Mr. Upcott in his Preface to Evelyn's *Miscellaneous Writings*, "had operated to the diminution of our woods and forests.* Men were not planters but destroyers of wood, without thought of the future; but the Civil wars gave a final blow to the work of havock: the aged oaks, like the old families which owned them, were, by these enemies of all that was elegant and venerable, doomed to destruction: feeling their tenure insecure, and professing themselves against root and branch, either to be reimbursed their holy purchases, or for some other sordid respect, they were tempted not only to fell and cut down, but utterly extirpate, demolish, and raze, all those many goodly woods and forests, which our more prudent ancestors left standing for the service of their Country."

Evelyn's *Sylva* first Work printed by order of the Royal Society.

The Work of Evelyn was the first book printed by order of the Royal Society. "It sounded the trumpet of alarm to the Nation on the condition of the woods and forests, and awakened the landholders to a sense of their own and their Country's interests. He lived to know that many millions of forest trees had been propagated and planted at his instigation." And who can estimate the benefits he conferred? who can say, after reflecting on the Naval conflicts this Country has had to pass through since the time of that great man, how large a portion of our Naval glory is to be attributed to him?†

Laws enacted for making enclosures.

(346.) During the reigns of Charles II. and William III. laws were enacted for making enclosures in the Forest of Dean in Gloucestershire, and the New Forest in Hampshire; and had those wise and prudent measures been continued to be acted on with all

---

* From the records of the Royal Forests, it appears that in 1608 a survey was made of six of them. There was then found fit for Naval purposes 234,229 trees, and of decayed trees the enormous number of 263,145.

† Evelyn laboured to the end of his long life in giving to his *Sylva* all the perfection in his power; and at a late period we find him thus encouraging the planter with the promise of longevity: "It is observed that planters are often blessed with health and old age. The days of a tree are the days of my people, says the prophet Isaiah. *Hæc scripsi octogenarius*, and shall if God protract my years, and continue my health, be continually planting, till it shall please him to transplant me into those glorious regions above, planted with perennial groves and trees bearing immortal fruit." "While Britain," says Mr. D'Israeli, "retains her awful situation among the nations of Europe, the *Sylva* of Evelyn will endure with her triumphant oaks. It was an author in his studious retreat, who, casting a prophetic eye on the Age we live in, secured the late victories of our Naval sovereignty. Inquire at the Admiralty how the fleets of Nelson have been constructed, and they can tell you that it was with the oaks which the genius of Evelyn had planted."

Evelyn says, "So precious was the esteem of the oak, that of old there was an express law among the Twelve Tables concerning the very gathering of the acorns, though they should be found fallen in another man's ground."

the energy our insular situation ought to have commanded, much of that anxiety which the enormous consumption of the last war produced, could not have occurred. The first great advance in the price of oak timber took place soon after the Restoration.

In 1771 a Committee of the House of Commons appointed respecting oak timber.

(347.) In 1771 a Committee of the House of Commons was appointed to inquire into the state of oak timber throughout the Kingdom; but singularly enough, from a difference of opinion, or defect of evidence, or a wish to avoid giving alarm, the Committee prayed to have that part of its order discharged which required them to report their opinion. In the following year, the Legislature interfered to prevent the East India Company from building ships in England until the amount of their tonnage should be reduced to 45,000 tons, affording by inference what that opinion was. In 1783, when the six Royal Forests alluded to in a preceding note were surveyed, it was found that the trees fit for Naval purposes amounted only to 50,455, and decayed trees to 35,554, exhibiting a decrease from 1608 of nearly four-fifths. There is, also, reason for believing that a corresponding diminution had taken place in all the Royal Forests. The quantity of English oak timber consumed for the Navy, from October 1760 to December 1788, amounted to 1,276,362 loads.

In 1788 Committee re-appointed to examine into the alarming state of our forests.

(348.) In 1788 the consideration of the subject was renewed with more energy, and a better prospect of success. The state of our woods and forests had begun to excite the most serious inquiry in Parliament. The immense expenditure of wood, particularly of that technically called compass timber, filled all thinking men with a well-grounded apprehension that our supply might fall very far short of the demand; and this alarm in all probability would have been realized, but for the happy introduction of iron, which during the War of the French Revolution had in so many ways been employed with advantage in the practical Arts. It seems to have been admitted on all hands, that prior to the period last adverted to, there had been a most extravagant waste of oak timber, a waste not only injurious to the financial resources of the Country, but also to the production of the article itself. Trees were felled in a premature state without consideration, nor was any care taken that their places should be supplied by a younger stock.* Men thought only of the present, anxious no doubt for their Country's good, but without that portion of wholesome care, which in every condition of life is the main spring of all transcendent and long-continued exertions. The amount of private shipping had increased during the sanguinary conflict here adverted to, from 1,300,000 tons to 2,500,000; that of the East India Company during the same period from 79,000 tons to 115,000; and the Navy, rising in gigantic power with all our difficulties, augmenting from 400,000 to 800,000 tons. And if in addition to all this we reflect, how greatly the manufacturing energies of the Country had been quickened; how on the right hand and on the left, in districts hitherto unblest by the presence of the Mechanical Arts, mills and enormous erections of machinery were in abundance created; docks, dock gates, slips, sluices, and piers, boats, barges, and bridges, in all our harbours; the operations of mining, extensive coal works; the pursuits of agriculture; the construction of innumerable barracks; the demands of the ordnance;—in all these and many more, oak timber being required in an abundance unthought of by the most sanguine speculator of a former Age;—when upwards of 100 sail of the line were in active commission, 160 frigates, 200 sloops, besides bombs, gun-brigs, cutters, schooners, &c., together with an immense fleet in ordinary, performing various offices: no wonder when all these combined causes were in full activity and play, and the price of the article, the sure criterion of the stock in hand, began to augment with the most rapid strides, that the public attention was aroused, and that Parliament in all right energy and power took up the question. It was calculated about this time that the whole consumption of oak for the Royal Navy, the East India Company, the Merchant Service, the internal demands for buildings of different kinds, canals, machinery, docks, &c. amounted to 4,015,000 tons.

Great preparations made in 1808 to meet the coming evil.

(349.) Accordingly in 1808, when the last embers of the hope of Peace had well nigh expired, and when men began to fear that a contest already unexampled in its fury and expense might yet be indefinitely prolonged, the Commissioners of Woods and Forests began to make active arrangements to meet the coming evil. In 1812 they made their first Report, and afforded some data by which a proper notion might be formed of our condition. Taking the tonnage of the Navy, said they, in 1806, at 776,087 tons, it would require, at the rate of one load and a half to a ton, the enormous quantity of 1,164,085 loads to build such a Navy; and supposing the average

Loads of timber necessary to build such a Navy as ours.

---

* Evelyn in his Letter to Mr. Aubrey remarked, that where goodly oaks grew and were cut down by his grandfather a hundred years before, beech only was then to be seen. He saw this to be an evil, and how has the evil multiplied and spread since his time! Arthur Young was of opinion, that in the Counties best adapted for the growth of oak, Kent, Sussex, &c. not one acre has been planted for fifty acres of wood-land that has been grubbed up. From the time of the *Domesday-book* down to 1792 there was a gradual diminution of wood-land. A competent person remarked in 1813, that if we except the Royal Forests, and perhaps the estates of some half a dozen great landholders, such as the Dukes of Devonshire, Norfolk, Portland, Newcastle, &c., it may be doubted whether any thing like a regular plantation of oak timber has taken place for the sixty years preceding.

It has been remarked, that the quantity of acorns which the oak bears, has made many people suppose, that Nature has taken care to renew a supply for us; and that of this vast quantity of seed, which annually falls, there will always be a superabundant supply of young trees, growing up in the place of the old ones; but experience proves that this is by no means the case. The greater number of these fallen acorns is devoured by many different animals, for whose nourishment Nature has provided that abundance of them; and of those which escape this fate, we are to consider how few can come to perfection, from the natural accidents to which they are unavoidably exposed. Acorns fall on a covered ground, where dead leaves and decayed branches of trees usually prevent their touching the earth; or if circumstances are more favourable, and they are enabled to shoot, it is merely from the surface, where they are, from the slowness of their growth, liable, while very tender, to the influences of frost; and added to this, it is very difficult for such tender plants as the young seedlings of these to find room for growth or nourishment among the roots of other trees spreading every way. The continual shade and want of free air also must render them very weakly and irregular in their growth, even supposing they are able to surmount all other difficulties.

It is, indeed, certain, that oaks are frequently met with among the underwood of forests, but this is only the case in spots where there has been a vacancy or opening; and that usually, where there are not, nor have at any time been oaks in the neighbourhood of the spot. Those trees which grow at a distance, result most likely from the accidental acorns brought thither by birds. This is an instance familiarly verified, by observing, that there are frequently little bushes near woods, which, though of white-thorn, or other trees, are usually surrounded and ornamented with young oaks. Jays and like carnivorous birds are the real authors of these crops.

Naval Architecture.

duration of a ship to be fourteen years, and there are many strong reasons for believing that this is too highly rated, an annual amount of 83,149 loads would be required, exclusive of repairs, which they estimate at 27,000 loads, making in the whole about 110,000 loads, towards which, however, they thought the bravery of British seamen might yearly afford 21,341 loads in the shape of prizes;* and from other sources than British oak 28,659 loads might be drawn, leaving a demand of 60,000 loads annually for the oak necessary for supporting in its then unexampled magnitude, the whole British Navy, including ships of war of all sorts, which may be regarded as equivalent to twenty 74-gun ships, containing one with another as constructed at that time, about 2000 tons, or 3000 loads of timber.

Annual demand in loads on this hypothesis.

Number of trees necessary for a ship of the line.

(350.) Now it has been estimated on an average, that of such oak trees as are necessary for constructing ships of the line, forty cover an acre of ground. Hence 50 acres of land, stocked at this rate with the finest trees, would be necessary for the construction of such a ship; and, consequently, 1000 acres for the twenty ships assumed as the annual consumption. Now, the oak, slow of growth, requires at least a century to bring it to maturity; and hence 100,000 acres would be required to keep up a successive supply for maintaining a navy of 700,000 or 800,000 tons. The Commissioners hence observed, that as there were 20,000,000 of acres of waste land in the Kingdom, a two-hundredth part set aside for planting, would at once furnish the whole quantity wanted for the Navy.

..mber of ..es necessary to ..ep up a ..ply of

Objections to this computation.

(351.) This computation, it has been remarked, is very considerably overrated. It proceeded on one great and melancholy hypothesis,—perpetual war, and an amount of tonnage more than double its present actual amount. Added to which it was also questioned, whether fourteen years was not too low an estimate for the average duration of ships; but after what we have seen of the ravages of dry rot, we prefer calculating on the safe side. Assuming, however, with the author of a statement of apparently good authority, made in the midst of the War, the actual tonnage kept in commission to be 400,000 tons, and the average duration of a ship of war to be 12½ years, there would be required an annual supply of tonnage to preserve the Navy in this state, amounting to 32,000 tons, or 48,000 loads of timber. According to the hypothesis before alluded to of the consumption for a 74-gun ship, these 48,000 loads would build 8 sail of the line and 16 frigates. Allowing one-fourth more for casualties, the annual consumption would be 60,000 loads, or 40,000 full-grown trees, of which thirty-five will stand on an acre. The quantity of timber, therefore, necessary for a 74-gun ship will occupy 57 acres of land,† and the annual demand will be the produce of 1140 acres. Allowing, also, only 90 years for the oak to arrive at perfection, there ought now to be standing 120,600 acres of oak plantation, and an annual felling and planting, in perpetual rotation of 1140 acres, to meet the consumption of the Navy alone. Large as this may seem, it is little more than 21 acres for each County in England and Wales; which is not equal to the belt surrounding the park and pleasure-grounds of many estates.*

Naval Architecture.

Further remarks on the computation.

(352.) This calculation proceeds on the supposition that every acre of the great surface of land referred to, is covered with timber fit for the purposes of ship-building; and that the greatest possible care is taken to nurse the plantations up to that standard. It may, however, be reasonably doubted, if we take the average condition of the Country into consideration, whether more than one-tenth of that number could be found on a single acre. Adopting also the ratio fixed on by some able writers, that the quantity of oak timber consumed in the Navy is only a tenth part of the whole consumption of the Country, it is evident that upwards of 12,000,000 of acres would be necessary to satisfy the whole demand. We have no means of answering the question whether such a quantity exists or not; but we know, that long before the conclusion of the War, a scarcity began to be felt, especially of the larger kind of timber fit for ships of the line.

Our duty at this time to encourage in every way the growth of oak.

(353.) This Essay is, however, written under the favourable circumstances of Peace, and when the difficulties we have passed through exist in our minds only as important Historical facts. It is our duty in a season of such a kind to look around, to husband our resources, and so to augment them as to enable us to enter with confidence into those untried scenes which may yet be in store for us. Not only is it our duty to encourage the growth of oaks, but also to keep our attention steadily directed to the timber to be found in our Colonial possessions. It has been truly observed, that the superior quality and abundance of the teak timber of India, and the Naval establishments in that Country, are available resources for keeping up our Naval strength, far too important to be in any way neglected.

* The splendid Naval achievements of the late War prove that this was not an improper supposition. During that War, England seemed to have swept from the Ocean the fleets of her enemies. There were captured or destroyed during that arduous conflict 156 sail of the line, 382 large frigates, and 662 corvettes, in all 2506 sail of vessels of war. It appears, also, that on the 30th September, 1811, there were prize ships, admitted to registry, and added to the commercial Navy of Great Britain, no less than 4023 ships, measuring 536,240 tons.

† On the hypothesis of 35 trees growing on a single acre, it will require for the building of a 120-gun ship, according to the present mode of construction, 168 acres of land; of an 80-gun ship 124 acres; of a 74-gun ship 103 acres; of a 52-gun frigate 68 acres; of a 46-gun frigate 51⅓ acres; of a 28-gun ship 27⅓ acres; of an 18-gun corvette 18 acres; of an 18-gun brig 13½ acres; of a 10-gun brig 9⅔ acres; of a schooner 7 acres, and of a cutter 5¼ acres. For one ship of each of these classes, 595 acres of land would be necessary, stocked according to the hypothesis adverted to.

* At the time Lord Glenbervie was Surveyor General of the Woods, &c., he reckoned in his first Report that 60,000 acres might be obtained from the several Royal Forests; and that the remaining 40,000 might probably be found among the forest lands in the Duchy of Lancaster, from Needwood forest, 3000 acres of which were appropriated to the Crown, from allotments to the Crown on the division of wastes and commons, by purchase, or otherwise, of lands locally situated within the different Royal Forests occupied by individuals either by legal title or by encroachments, by purchase of wood-lands from private owners, and by purchasing out, or refusing the renewal of, Crown leases of land containing oak coppices or land fit for the growth of oak. To which might be added a reservation in every Enclosure Bill of a certain proportion to be set apart for the express purpose of planting oaks, besides an obligatory clause to plant oaks in the fences at limited distances. His Lordship also thought that the 100,000 acres should be enclosed and planted at the rate of about 4000 acres annually, which would complete the whole in about 25 years. The present and intermediate supply will be obtained from timber now ready for felling, and in its different stages in the Royal Forests, on private estates, from thinnings of the new plantations for inferior purposes, by importations of foreign oak, and by the use of other kinds of timber. At the time this Report was drawn up 35,000 acres had already been appropriated in this way; and since that time our energies have not been slackened.

Naval Architecture.

The supply which the forests of India yield, if not made use of in ship-building, must, like many other resources of that splendid region, be entirely lost to the nation.

Teak.

(354.) The teak forests are in the Ghauts of the interior, both to the Northward and Southward of Bombay, but chiefly in the latter direction. Lord Wellesley was the first, in consequence of a communication from Lord Melville, to cause the teak forests of Western India to be examined, and measures were adopted for procuring a regular supply from them. The East India Company purchased various wood-lands, and the supply seems now inexhaustible.

Its quality.

(355.) The quality of teak is in many respects preferable to that of oak for ship-building. Alternate exposure to a vertical sun, and to the drenching rain of the wet monsoons, which would rend in pieces European oak, produces no injurious effects upon teak. Many of the upright timbers for securing the stays in the Old Docks at Bombay have stood more than forty years with paint or tar, and in 1812 were still as perfect as when first erected. A piece of the same wood also, taken out of a gate of one of Tippoo's forts in Canara, which had been exposed to every change of weather for more than half a century, when brought to Bombay was ascertained to be unimpaired, with nails, which had secured it, quite free from corrosion or rust, and as sound as when first driven. The Turkish flag ship at Bussorah was built by Nadir Shah, and after seventy years, when examined at Bombay, was found perfectly sound. The Hercules of 485 tons, built at the same place in 1763, when captured by the French in 1783, was entire in every part; and the Milford of 679 tons, after constant employment between China and Europe for 24 years, was examined, and no timber found which required shifting. Her teak main mast continued in her twenty-one years, when, being partially sprung, it was converted into a main mast for a smaller vessel. Teak possesses the valuable property of preserving iron, while oak destroys it. A piece of teak plank, which had been bolted to the side of the Chiffone frigate, was removed at the end of eight years. That part of the iron bolt buried in the teak was found perfectly good, whereas that which had been in the oak was totally corroded.

Larch.

(356.) Much has been said in favour of larch for the purposes of ship-building. So fully was the Empress Catherine impressed with its value, that the exportation of it from Russia was at one time prohibited. The rapidity of its growth is so great, that it has been found to double in diameter that of the oak in the same given time, and hence to produce four times the quantity of timber. From several experiments it has been found not inferior in strength, toughness, and elasticity to oak. The Dukes of Athol and Montrose, Lord Fife, and several other great landholders in Scotland, have made very extensive plantations of this tree and the Scotch fir, which are rapidly rising into magnificent forests, and will enable us in future years to diminish the consumption of our native oak.

Where timber fit for ship-building may be obtained.

(357.) Trinidad contains about a million and a half of acres, two-thirds of which, at least, are covered with wood, and wholly the property of the Crown. The Spanish peons, or labourers, are extremely dexterous at felling and squaring timber, and work at a cheap rate. In Canada, Nova Scotia, and New Brunswick, also, we possess immense forests abounding with oak for ship-building. With all these Colonial resources, added to our own domestic supplies, and the great attention now paid to the rearing of the oak in our Royal Forests, we have little fear of obtaining an abundant quantity whenever the warlike energies of the nation may be again called into exercise.

(358.) In the Mediterranean Islands, in the Morea, in Albania, Dalmatia, and Croatia, the finest oak timber, in point of size and shape, is most abundant.

Report of French Commission on timber.

(359.) In the *Annales Maritimes* for June 1828 is a Report of a Commission charged by the French Government with the examination of woods imported from Africa. Of the *cail cedra* it was said, that though less flexible, it is tougher than oak, and being as strong, without being heavier, may be quite as advantageously employed in Naval construction. The *gonakier*, almost as flexible as oak, and at the same time possessing one half more strength and toughness, is better calculated for the frames of ships. The *dethard*, of equal strength with oak, is more flexible, but has not so much elasticity. It appears very well adapted for planking, and as a substitute for compass timber. The *turtosa* has rather less flexibility than oak, but is superior to it in every other respect.

Timber suitable for mast-making.

(360.) For many purposes, if timber have strength and durability, it possesses every necessary quality; but there are some applications of wood in which other qualities are necessary, such as flexibility, elasticity, and lightness. This is particularly the case in mast-making, a branch of ship-building on which the most important considerations depend. If a mast possesses so great a degree of rigidity as not to yield to the sudden shocks to which it is subject, it must soon become fractured; and if its resilience when bent be not sufficient to cause it to recover its true position, it is rendered weaker at every impulse.

Fir and pine.

(361.) The timber commonly used for masts is fir and pine, distinguished according to the character of their leaves and cones. By mast-makers it is distinguished by the name of the place from which it is imported, as the Norway and Riga firs, Canada red and white pines, &c. According to Mr. Fincham, the timber that possesses in the greatest degree the qualities best suited for masting, is the *pinus silvestris Genevensis vulgaris*, abounding in the vast forests of Russia, Norway, and Poland. The most esteemed is from the Ukraine and Livonia, and is brought down the Dwina. It is commonly called Riga from the port from which it is shipped, in the same way as the Adriatic fir derives its name from being shipped in the Adriatic. The different firs and pines, besides those of the North, used for masting the Royal Navy of Great Britain, and likewise to a great extent her commercial Navy, are principally those from Canada, with some from Nova Scotia, and a few from Scotland. The timber from Canada consists chiefly of the *pinus strobus*, or what is commonly called the Weymouth, or white masting pine; and the white, red, and black spruce, *pinus Canadensis*. The Scotch fir, *pinus silvestris*, is common in the Highlands of Scotland, as well as in Norway, Denmark, and Sweden.

Remarks on varieties.

Further remarks on varieties and uses of Pine. Poon.

(362.) Standing masts are generally made of yellow pine, and topmasts of red. The white, red, and black spruce are but little employed, excepting for small spars. The Adriatic fir is frequently used for the masts of cutters and other small vessels, but its qualities are not very good. Timber denominated Poon has been partially used for masting ships built in India; and the Cowrie brought from New Zealand has been employed

Naval Architecture.

for small standing masts, and for topmasts even for a first-rate. This latter possesses many of the most esteemed qualities for masting.

French obtain supplies from Corsica, Pyrenees, &c.

(363.) The French, according to Forfait and others, have received considerable supplies from Corsica, from the Pyrenees, from Catalonia, Savoy, from the neighbourhood of Mont Blanc, Puy de Dome, and Cantal. These firs, however, contain but little resinous matter. The heart is porous and the grain close, and their flexibility is but very trifling. They soon become dry and break under very slight strains.

Turks, from shores of Black Sea.

(364.) The Turks obtain excellent firs from the shores of the Black Sea. They are commonly of the species denominated *pinus pinea*, and *pinus laricis*. They are but little inferior to the trees of the North.

Great practical skill requisite to judge of wood.

(365.) It requires great practical skill and experience to judge of the qualities of any kind of wood. In the selection of firs for masting, the climate, aspect, and soil in which they grow must be attentively considered. To judge of the qualities of trees while standing, is the duty of those employed in the forests; while the mast-maker makes his selection from the trees when felled, and judges of them as timber. The most desirable firs have a fine and close grain, with the ligneous layers closely blended together, and their annual concentric circles finely and firmly connected, decreasing gradually from the heart to the sap. The nearer these layers approach to circles or ellipses, the less likely is the timber to be defective. They are, generally, highly charged with resin, giving strength and elasticity, preserving the timber from insects, and preventing fermentation and decay. The colour should be of a clear or bright yellow, with a reddish cast alternately. The smell of Riga and other firs of this quality, should be strongly resinous, especially when they are exposed to the sun, or their shavings are rubbed between the fingers. In cases where the layers are open, with pale red tints near the heart, and white spots intermixed; or where they are of a dark red colour with the resinous particles of a blackish colour, the timber is in a state of decay. When firs are cut transversely, and not of an uniform colour, but interspersed with veins, and the smell is entirely gone or become fetid, they may be considered as past their prime, and approaching a state of decay. In some yellow and red pines, the degree of unsoundness is indicated by the offensiveness of the smell, and alternate layers of a foxy-brown, or red colour, will break out before the sharpest plane on being wrought.

What are the most desirable firs.

How the experienced mast-maker judges.

(366.) The experienced mast-maker, says Mr. Fincham, forms his opinion of the quality of a stick, not only from the colour, smell, and appearance of the grain, but also by its working; for as a stick is more or less fragile, the greater or less difficulty he has in separating its parts, as he chops them off. If the timber is good, its parts, on being separated, appear stringy, and oppose a strong adhesion, and the shavings from the plane will bear to be twisted two or three times round the fingers; whereas, if the stick be of a bad quality, or in a state of decay, and has lost its resinous qualities, the chips and shavings come off short and brittle, and with much greater ease.

Further remarks on quality.

(367.) Those kinds of timber that have but little or no resin, and whose colour is of a whitish or light brown cast, and are of rather a coarse grain, as the Adriatic, Norway, &c., will, as they become dry, though they maintain their strength and resilience for a considerable time, be so rigid that they will always be subject to break, by any sudden impulse, without warning, especially if they are kept in dry stores for a long time.

Naval Architecture.

(368.) The Riga and other timbers containing a proper quantity of resin, and the red pine, from the fineness and closeness of its grain, and the adhesiveness of its fibre, not only maintain their resilience, but their strength and flexibility much longer, even to a dry state.

Cowrie.

(369.) The Cowrie possesses advantages over most other timber, from the firmness of its grain, and the uniformity of its texture. The experiments which have been made on this timber, compared with the Riga, Dantzic, and other esteemed firs, justify the conclusion that it possesses equally good qualities with these timbers, for all the purposes for which they are generally used. When exposed to the weather, it appears less liable to shrink, and stands equally well with them. The Cowrie spars that have been brought to England, appear but a little beyond saplings, since many of the full grown trees are said to exceed 30 feet in girth, and to continue the full size to nearly 60 feet from the ground. Their common diameter is from three to six feet, and their length frequently from 90 to 100 feet clear of branches.

Valuable information to be derived from practical men.

(370.) These are some of the results which long practical experience affords, and are the only solid groundworks of improvement in the Mechanical Arts. In the various applications of timber, and in none more so than in mast-making, accurate experience is of the greatest importance. The Philosopher, as he passes through a workshop, learns to value men who, at every step, may afford him some useful information; something probably which had been handed down by tradition from one generation of workmen to another, but with which he is not acquainted. And that knowledge of this kind is indispensable, if he wishes to gain an accurate acquaintance with the Arts of life, will be readily conceded by him whose mind has been properly disciplined and trained; who regards all the practical Arts as helpmates to Science; and as the only certain foundations for the very best departments of our knowledge.

Dry Rot, and other Sources of Decay.

Dry rot, &c.

(371.) One of the most formidable evils the Navy of England has had to contend with is the dry rot; a subtle enemy, more terrible than the bullets of the greatest cannon, decomposing the fibres of timber, depriving the largest trees of all their strength, and in a few years reducing the whole fabric of the noblest vessel to a mass of dry dust.

Great developement of it in our own times.

(372.) It has been reserved for our days to see this destructive agent develope itself with gigantic power, attacking many of our modern built houses, and sapping with irresistible energy our finest built ships. The inquiring mind naturally asks, how vessels built half a century ago are more durable than these constructed at the present time; to what circumstance it is to be attributed that the beautiful roof of Westminster Hall is as sound and as perfect as on the day it was built; why the mansions and Baronial halls of the olden time seem destined to survive the modern built villa; why some of our oldest ships should exhibit fewer elements of decay than the vessels on which all the resources of Modern Art have been bestowed?

Masts.

Naval Architecture.

Dry rot coeval with timber trees.

Public attention first directed to it in 1810.

(373.) There can be no doubt that this disease, whatever it be,—for its nature and cure seem almost equally unknown, must have been coeval with timber trees themselves, though not known by its present name, or exhibiting so formidable examples of its power, until about the middle of the last Century.* About the year 1810,† however, the public attention was first seriously awakened to its importance, in consequence of the Queen Charlotte, a noble first-rate ship of war, having been launched at Deptford, sent round to Plymouth under jury masts in 1811, found too rotten to be seaworthy, and in the following year undergoing a repair, amounting, it is said, to £30,000. All her upper works were infected with dry rot; the ends of her beams, carlings, and ledges, and the joinings of her planks being covered with a mouldy, fibrous, and reticulated crust, the portions of her timbers so covered being altogether rotten. It would be endless to enumerate the abundant speculations to which this remarkable occurrence gave birth. Theories of its origin, remedies for its cure were offered on all sides; and while the severest critic could not but applaud the zeal and patriotic spirit which animated their authors, the melancholy conviction was forced on his attention, that neither for one nor the other was any sound or rational opinion offered.

Numerous theories and remedies consequent thereon.

(374.) Among other objects of discussion was the inquiry whether the common rot and the dry rot were the same; and it was soon perceived that the two were essentially different,—different in their origin, and very different in their modes of operation. The common rot, it was remarked, is a gradual decay of the fibre of the wood, more or less accelerated by the uncertain action of wind, heat, and moisture on its surface; its progress internally being greatest when the timber is constantly exposed to alternations of wet and drought, as exemplified in the rapid decay of that part of a post which is close to the surface of the earth, while all above and below is perfectly sound; and least, when constantly soaked in water, or kept constantly dry, exposed to a free current of air, or excluded entirely from it.

Common rot and dry rot.

Nature of the common rot.

(375.) The dry rot, on the contrary, commences its ravages internally, and is but little affected by any external circumstance, excepting that of heat. Its external characters are differently described by different observers. By some a fine mouldy coating has been observed to spread over the wood, of a brownish-yellow or dirty white, which soon begins to resemble in form and structure some of the beautiful ramified algæ or seaweeds. This in a little time becomes more compact, the interstices being so completely filled up as to give to the whole the appearance of leather. By others it has been represented as fibres running over the surface in endless ramifications, resembling the nervous fibres of leaves; the interstices being filled with a spongy-like substance assuming the character of that order of Cryptogamous plants distinguished by the name of *fungus*.* According to Mr. Wade, the wood at first swells; after some time it changes its colour, and then emits gases which have a mouldy or musty smell. In more advanced stages, the wood cracks transversely, and in its latter stages becomes pulverulent, forming vegetable earth; and, generally, in some of these stages of decay, the different species of fungus are found to vegetate on the mass.

Nature of dry rot.

Its external characters.

Different descriptions of it.

(376.) These appearances do not, however, invariably happen, the surface of the diseased timber sometimes remaining unchanged, while the process of rotting is going on within; and however sound the surface may be, the whole of the exterior fibres become decomposed, presenting a mass of dust inclosed within a thin external shell. No charring of the surface, no external application of paint, tar, or varnish, will stop its ravages where the seeds of the dry rot exist in a situation favourable for their growth, though the external character of mouldiness may by such means be prevented from appearing on the surface.

Diversity in its appearance.

(377.) This terribly destructive agent was discovered in all our harbours, and sapping the vitals of our ships more or less, wherever they were found on the sea. From the best information that can be gathered, it appears, that to the rapid construction of our ships during the late War, may be attributed their very extraordinary decay. When Lord Spencer quitted the Admiralty in 1801, it has been generally supposed that he left an efficient fleet, but this was by no means the case. It was numerous indeed, but many of the ships were nearly worn out. Lord St. Vincent, his successor, determined to build no more ships in merchants' yards, and the King's yards were almost wholly occupied in patching up those actually in commission, and those brought forward from the ordinary. In 1804, when Lord Melville succeeded to the Admiralty, the Navy was wholly inadequate to the situation of the Country; scarcely one of the ships in commission having more than three years to run, most of them but two, and many only one; a few, and but a few, new ones were slowly coming forward in the King's yards, and none in the merchants' yards. Thus circumstanced, recourse was had to private builders, who were wholly unprepared with materials. Contracts, however, were entered into at advanced prices, the axe was set to work, and trees which were one year growing in the forest, were in the next floating on the ocean; and up to the termination of the War, so closely did the demand press upon the supply, that few, if any, ships were built in the Royal yards with

Rapid construction of ships the cause of their decay

Lord St. Vincent determined to build no more ships in merchants' yards.

Dangerous state of the Navy in 1804.

Lord Melville compelled to have recourse to private builders.

* Mr. Knowles, in his inquiry into the means which have been taken to preserve the Navy, cites the 14th Chapter of *Leviticus*, in which dry rot is accurately described under the name of "leprosy in houses," and the same remedies directed to be applied, which have been practised with success in our own time. That dry rot also existed in the latter part of the XVIIth Century may be inferred from Mr. Pepys, who gathered toad stools in their holds "as big as his fists."

† The term "dry rot" was not inserted in any official document earlier than 1808.

* The Author of this Essay, early in life, had a book-case with close doors in its lower part, in a study on the ground-floor of a new house. Into this lower compartment of the book-case, he had put a number of books he was not in the habit of using, together with many MSS. The doors were not opened for many months, but one day finding it necessary to refer to some Work, he opened the doors, and to his great amazement saw every opening filled with the most beautiful varieties of fungus. On examining the books, some of them crumbled beneath the slightest touch; and between all their leaves, the finest layers of a very thin leather-like substance were found. This substance had removed all traces of writing from many of the MSS., and many fell into the finest powder. The lower part of the book case was completely rotten, and on examining the wood-work of the house, such as the lower partitions, floors, stairs, &c., nearly the whole was found completely decayed. In a short time the staircase must have been broken down even by a little child treading on it, so active had been the work of destruction. He lost several rare and valuable Works, and some important MSS. on this occasion.

Naval Architecture.

well-seasoned timber. Hence the probable origin of an evil, which at one time filled the stoutest hearts with dismay, and reparation of the ravages of which has cost the Country millions.

Scarcity of oak.

(378.) The scarcity of our own noble oak contributed greatly to accelerate this fearful state of things. Its employment in the same vessel in a seasoned and unseasoned state, and its mixture with different kinds of foreign timber, led to the most disastrous results. The Queen Charlotte before adverted to was nearly seven years in building. Of the timber employed in her construction, some was seasoned and some quite green. Part of it consisted of Canada oak, and part of pitch pine, both peculiarly susceptible of dry rot. Her timbers were covered with as many species of the *boletus* as there were different kinds of wood employed in her construction. During our long protracted War we had line of battle ships constructed in the Royal Dockyards entirely of oak from Holstein, and frigates in the same establishments altogether of fir imported from the Baltic. In the river Thames, also, we had gun-brigs built of this latter material, and numerous frigates of the red pine, pitch pine, and yellow pine of America. At Bombay, Calcutta, and Cochin, ships of the line and vessels of other classes were formed wholly from teak. At Prince of Wales's Island, frigates were constructed of the different sorts of wood abounding in that Island; at Halifax, ships of birch, red pine, and oak; at Bermuda numerous vessels entirely of cedar. The Athol, also, was built in England entirely of larch. From Sierra Leone, timber was imported for ship-building. Of these varieties, teak is the most durable, and the red pine of America the least so. Frigates framed from this latter wood seldom lasted longer than four or five years.

Mixing different kinds of wood injurious. Seasoned with unseasoned.

Varieties of wood employed in our Dockyards during the War.

Examples of bad building.

(379.) As practically authentic examples of the evils resulting from the careless employment of unseasoned timber,—of bad workmanship unchecked by vigilant superintending officers,—as examples, we fear we may say, of those tremendous frauds, which to a greater or less degree prevailed in most of our public departments at this time, we select from a host that might be adduced the following. The Rodney, line of battle ship, built in the private yard of Barnard, was launched in 1809. She had scarcely put to sea, when, owing to the unseasoned state of her timber, all her planks became loose, and it was necessary to bring her home from the Mediterranean in 1812 to be paid off.* The three King's master-shipwrights, who examined her, reported that they found a bolt in the chock of a beam not passing through the ship's side, and that a hole bored for a bolt had only putty put into it. The Dublin, built in Brent's yard, was launched in February 1812, put in commission in the following August, sent upon a cruise towards Madeira and the Western Islands in December, from which she returned to Plymouth in February 1813, in so dreadful a state, that she was ordered to be paid off. The officers of the Plymouth yard stated in their report of this ship, that "her defects exceeded any thing they had ever witnessed in a new ship."

Disgraceful workmanship.

Enormous cost of repairs.

(380.) An idea of the enormous cost of repairs may be gathered from the following brief Table, part only of a catalogue which fills the mind with the deepest indignation:

	When Built.	First Cost.	Time of Service before being docked. Yrs.	Mos.	Cost of Repairs.	When paid off.
Superb..	1798	£38,647	2	6	£47,283	1809
Ajax....	1798	39,039	0	5	26,683	1802
Achille .	1798	38,450	1	5	25,646	1802
Spencer.	1800	36,249	2	9	43,748	1802

In two cases out of the four the repairs considerably exceeded the original costs of the vessels. The surveying officer who superintended the building of the Ajax,

* The resident overseer who in such cases superintended the building of a ship, was what was then denominated a quarterman, one degree above a common carpenter, at a salary from £160 to £180 a year. This person was appointed to overlook and to check the work of a Body of men, who were not very easily controlled. It was stated in evidence, before the Select Committee of the House of Commons appointed to inquire into the subject, that a common shipwright then earned a guinea a day in job work. It was hardly to be expected, therefore, that an officer with so small a salary could resist the combinations of men gaining wages so high, particularly when joined by all the weight and influence of the contractors. The *inspection*, therefore, was a nullity. It was utterly impossible for one individual to examine minutely into all the operations of the great number of men employed at the same time on the different parts of so large a machine as a 74-gun ship. While superintending the work of one gang on one side of the ship, another gang may be employed, to adopt the strong language of a Quarterly Reviewer, "*clenching devils*," as they did in the Albion; or driving "*short bolts*," as was the case in the Ardent; or filling up bolt holes and the rifts in *shaky* timber with paint and putty.

Equally unsatisfactory was the resurvey of the ship when she was received into the King's yards. We quote the reply of the builder and his assistants when called on to explain their conduct with regard to the Rodney.

"The Rodney was carefully inspected by us in the usual manner, and reported that, as far as practicable for us to form an opinion, the works appeared to be executed in a workmanlike manner, and agreeably to the terms of the contract; but it is not *possible for us to form any opinion of the internal parts of the work*, which can be known only to those who inspect the whole of the work in the progress of building."

How very imperfect an estimate is to be formed from the survey of a ship may be collected from the following fact: four 74-gun ships, the Resolution, the Thunderer, the Monarch, and the Culloden, were examined by the Dock-yard officers, and reported as fit to be cut down and converted into razées to be employed against the large American frigates. They were taken in succession into dock for that purpose, but every one of them, on being *opened*, was found unfit for further service, and ordered to be broken up.

That a better system was employed in the King's yards there can be no doubt, and if the ships built in the Royal Dock-yards decayed, it arose from the material necessarily employed, and not from defective workmanship. In *practical* ship-building we surpass every other people; and a good judge of this kind of carpentry need only walk through our Dock-yards, and minutely inspect the ships there building and repairing, to be convinced that the most careful attention is bestowed on this important particular. There is, indeed, so complete a system of inspection and responsibility, as to make it quite impossible to slur over the workmanship in the same slovenly manner as was done in the private yards. The master-shipwright is charged with the general and unremitting superintendence of all the works in each yard; his assistants superintend and control the foremen; they in their turn check the leading men, and the leading men are responsible for the divisions under them. The foremen, being salary officers, have no participation in the earnings of the gang, no interest in the work being slovenly or rapidly performed. On the contrary, the highest responsibility rests on them for its proper execution. An account is taken of every timber and plank that enters the ship, of every hole that is bored, every bolt that is clenched, and every treenail that is driven. The hours of labour are precisely regulated. Every shipwright must be punctual in his attendance, and decent and orderly in his behaviour; and hence it is no fault of the workmen, or of the officers who superintend them, if the ships built in the Royal Dock-yards decay. They can only convert the timber that is in store. The responsibility of providing proper materials rests with a higher quarter: in the times we are alluding to with the Navy Board, at the present time, now that that Board is abolished, with the Admiralty.

Naval Architecture.

stated in justification of his conduct, "That the unfitness and bad quality of the timber used in that ship, neither were, nor could be discovered by the surveying officers of the yard, as the defects (if any) were always hid by putty, and the surfaces of the beams, knees, riders, &c., covered over with three coats of paint."*

* The magnitude of the evils existing at this time in our ship-building, will amply apologize for the following Reports of the surveying officers of Chatham yard on the state of the Albion, built in a merchant's yard, and alluded to in a former note. Such Reports ought to read a lesson of the strongest kind to the future managers of our Navy.

Extract of a Copy of a Letter to the Navy Board, Chatham yard, April 1, 1811.

The Albion under repair in this yard, from her extraordinary defects, calls for a minute inspection, and a particular description of the causes that may be discovered, that have led to such uncommon complaints, in order to prevent similar occurrences.

We have taken a strake out of her bottom, at the run of the first and second futtock heads, when we discovered that the usual mode of fastening the plank by single and double boring the timbers alternately has not been attended to, a large portion of the timbers being only single bored, of course the ship has been deprived of a considerable quantity of fastenings, and the treenails that are driven appear much crippled from the strain that has been upon them; the plank at the run of the second futtock heads in particular, is not generally in contact with the timbers, nor was it in the first instance, for we discover that it is not in places the proper thickness.

The butts of the wales and the materials above are drawn apart in many places by the hogging of the ship, so that recourse has been had to the letting in of pieces at the butts, to make the calking stand.

In the hold, the foot waling was, from the orlop clamps down, a mass of defective matter; we, in consequence, unbolted the riders, and took it out, when we discovered the timbers of the frame and the opening sodden with filth. Had the ship been sunk in mud, her state could not have been worse; in places she appears to have been a prey to insects of different descriptions, for some of the openings were absolutely full of their remains.

In unbolting the riders, hooks, and crutches, we found many bolts broken, some *short*, and a few termed *devils*, or in other words *false clenches*; in the crutches we also found several bolts *ragged*, which we imagined was done in consequence of their being for an auger of a larger diameter than the bolt required, as rope yarns were wrapped round the bolts so served. A piece of gun-deck spirketing, and also a shift of foot waling was discovered to be chopped in, termed a Spanish burn.

The stern frame of the ship is fallen aft many inches, which may be seen by the carling under the gun-deck beam which rises to the throat of the deck transoms.

The thwartship's arms of the knees of the various decks are twisted from the sides of the beams, many of them sprung so as to be of little use to the ship, and a considerable quantity of the fore and aft bolts broken, many of the beams defective, and departed considerably from their original round, particularly the orlop; in fact, this ship presents a fabric of *complete debility*, arising principally from the *insufficiency of the workmanship*.

With respect to the *devil bolts*, as they are termed, or *false clenches*, we conceive the act so truly criminal, that we are humbly of opinion, that the Legislature should provide a punishment proportionate to the offence.

If it is judged proper to enact a penalty to prevent accidents in cases where the common stages are loaded with passengers beyond a limited number, of how much more consequence is it to prevent acts which may be the destruction of hundreds!

(Signed.) R. SEPPINGS. E. P. HELLYER. W. HUNT.

JOSEPH SPECK, THOMAS PARROTT, RICHARD PRICK, } Carpenters of the { Queen, Ramillies, Albion.

The warrant for the Navy Board ordering the repairs of this ship did not, it seems, embrace all that was necessary to be done; upon which the surveying officers again addressed the Board, as follows:

We can with great truth assure your Honourable Board, that our reason for making the representation was grounded on no other motive than that of doing our duty in a case where *great neglect* has taken place, from which *the Government has sustained a considerable loss, and a ship's company narrowly escaped shipwreck.*

We had flattered ourselves that our survey would have met with your Honourable Board's approbation, and so we humbly conceive it would, but we suspect *representations have been made to counteract what we have stated*; if that be the case, we should be happy to meet those on the spot that have advanced a contrary doctrine. Our suspicions that a different report has been given, arise from the mode of repair you have been pleased to direct; and which mode we consider has been adopted in consequence of representations made by the assistant *surveyor of the Navy*, who has, with the *merchant ship-builders*, visited this yard since our statement.

We have opened her abaft since our survey, by which we have discovered *great additional deficiency of workmanship*, and should contrary opinions have been given to that we have advanced, we are of opinion, those that have offered them should come and view the ship.

(Signed.) R. SEPPINGS. E. P. HELLYER. W. HUNT.

These horrible devils are not confined to the *Albion*. In the surveying officers' reports on the *Ardent* is the following passage: Several of the fore and aft bolts of the gun, upper, and quarter decks, also the forecastle, worked wholly out, and others partly so, in consequence *of many of the bolts being short*; some that worked out were only *five inches, and others nine inches long.*

(Signed.) JOSEPH TUCKER. J. ANCELL. EDWARD CHURCHILL. JAMES JAGOE.

The portion of the second Report, alluding to representations having been made to counteract the statements that had been afforded by the distinguished ship-builders whose names are attached to it, shows at once the nature of the influence that was exerted, and goes far to explain the abominable practices that prevailed in these private yards where King's ships were building.

(381.) In the Journal of Lord Sandwich's visitation of the Dock-yards in 1771, the following passage occurs. "Went on board the Ardent, found her in a total decay, her timber and plank rotted almost universally. This ship was built at Hull in 1764, and never was at sea; her prime cost was about £23,000, and her repairs are now estimated at £17,000. The cause of the great decay of this ship is attributed to her being hastily built." His Lordship adds: "no more ships to be built at Hull." Happy would it have been for the Country could this injunction respecting Hull have been extended in an after-time to all the private yards in the Kingdom; or if the necessities of the Kingdom required their assistance, that an effectual superintendence of them had been rigidly enforced.

Remarkable entry in the Journal of Lord Sandwich.

(382.) We have had so many examples of great durability in our Navy, that our regret at these instances of decay, cannot but be augmented when we reflect on them. The Royal William, a first-rate, built at Portsmouth in 1719, was among the ships sent to the relief of Gibraltar in 1782, and after the lapse of nearly a century, bore the flag of the Port Admiral at Spithead. The breaking up of this fine old ship was an object of considerable curiosity. Various reasons had been assigned for her extraordinary durability. It was supposed that her timber had undergone some artificial seasoning, that the plank and thick stuff had been burned instead of kilned, the ends and surfaces of the various parts charred, and that the process of *snail creeping*, or gouging out, in crooked channels the surfaces of the timbers and planks, was made use of to give a free circulation of air. It is understood, however, that no indications of charring, burning, or snail creeping could be traced, and that her timbers had undergone no other preparation than that of time and the weather. This remarkable vessel was built by Mr. Nash, and he took particular care when building her to employ only well-seasoned materials. It is also a singular fact in the history of this ship, that owing to an ignoble jealousy which existed between her builder and Sir Jacob Ackworth, Sir Jacob endeavouring in all things to lessen the merit of Mr. Nash, the Royal William was not for

Many examples of great durability of ships. Royal William.

Naval Architecture.

many years employed, and even a decree was on one occasion made for making her a hospital ship. "Thus," said Lord Sandwich, "that ship which has proved to be of as good qualities as any ship that was ever built, was lost to the public for many years, owing to a jealousy and ill will between two officers. Such feelings are the ruin of many great undertakings, and in the public departments ought to be checked in every possible way."

Sovereign of the Seas.

(383.) The Sovereign of the Seas, afterwards named the Royal Sovereign, was built at Woolwich in 1637, and stood forty-seven years' service. The Barfleur was built at Chatham in 1768, and in 1812 was still a good ship and under repair for further service. The Montague was launched at Chatham in 1779. After undergoing several repairs, she carried the flag of Admiral Sir Manly Dixon, the "Hero of the Lion" as he is called by the sailors, at Rio Janeiro. How different these examples from the Ocean, the Foudroyant, the St. Domingo, the Rodney, the Ajax, the Albion, and many others, which were falling to pieces within five years after launching, and some of them in less than three!

Satisfactory state of the British Navy at this time.

(384.) It is a consolatory reflection, however, after the really appalling considerations we have felt it our duty to go through, to state, that at the present time, the state of the British Navy is such as to warrant the most complete satisfaction in the general efficiency and soundness of our ships. The constant assertions of those authorities, whose situations make them necessarily acquainted with the general state of the Navy, and whose unremitting attention renders them most intimately acquainted with the minutest details of his Majesty's ships, are abundantly sufficient to remove every fear which its condition fifteen or twenty years ago could not but inspire.

Precautionary measures that have been adopted.

(385.) This great and desirable change has been brought about by various precautionary measures adopted by the late Navy Board, after reviewing all the plans that had been proposed by different ingenious individuals.* The methods at present adopted in his Majesty's Dock-yards for the preservation of timber, are such as have been suggested by an examination of its nature, and the circumstances under which it is placed in ships, and which have been proved by experience to have been well calculated to produce this desirable effect.

Placing timber under roofs and not in contact.

The principal of these—the placing timber under roofs, and keeping the logs apart from each other, is found an excellent method of seasoning timber, by admitting a free circulation of air without an exposure to the rain.

Immersion of timber in fresh and salt water.

Immersion of timber in water also is found to be an expeditious method of drawing out the juices of the wood; and salt water has been preferred to fresh, on account of the antiputrescent power of salt, which, though less effective on vegetable than on animal matter, is useful in checking the decay of timber.

Removing sap.

Also taking off the sap, which speedily becomes rotten, and preventing the communication of the decay to the adjoining heart wood.

Coating surfaces with tar.

Covering, likewise, the surfaces of timber with mineral tar or paint, thereby keeping the timber from being rent by the air, and preventing the seed of the fungus, which *may* be in the outer laminæ of the timber, from vegetating, by the exclusion of the atmospheric air from it. It is also particularly useful when two kinds of timber are brought together, by preventing the fermentation which would arise from the union of different vegetable principles.

Injection of tar.

The injection of tar and whitening into ships' bottoms, has been found also of very great benefit in preserving the timbers, by its preventing effectually the growth of the fungus; the openings between the timbers, which would otherwise be imperfectly filled, and the rents in the timbers, in which places the seed of the fungus would be most likely to vegetate, being by this means completely filled, the air, so necessary to vegetation, is excluded. It is probable that the great advantages of the injected tar, &c., into the interstices of the wood, are not yet fully known.

Building and repairing ships under roofs.

(386.) In addition to these preventives, ships are built and repaired under roofs, thereby preventing the rain from settling in the rents of the timbers and the openings between them. In the ships in ordinary, also, particular attention has been paid to their preservation, by erecting temporary roofs over them, taking down parts of the bulk heads in the hold, and leaving out streaks in the decks and openings in the truss work, between the ports, to promote a free circulation of air.

Free currents of air.

(387.) It is proper to observe, however, that the establishment of a free current of air through a ship, though of very great advantage in preventing decay, is, nevertheless, attended with the disadvantage of causing the timber to shrink, thereby impairing the strength of the fabric, by destroying in some degree the benefits arising from fitting the pieces of work closely together, technically called "faying well." The maximum advantage is therefore obtained by giving such a circulation of air as may be sufficient to prevent decay, without causing the timber to shrink too much. Experience is tending fast towards the discovery of the proper limit, towards which this principle may be carried with the greatest advantage to the service.

German oak timber very subject to dry rot.

(388.) The oak timber produced in the forests of Germany is remarkably subject to the dry rot. Hence the ships in the Scheldt, during the latter part of Buonaparte's career, were rapidly advancing in rottenness from this cause. The Chatham, a 74-gun ship, had the dry rot in her timbers when taken from the stocks in the Dock-yard of Flushing. The Rivoli, just off the stocks, at Malamacca near Venice, was also in the same state. This latter ship was built of oak cut from the Eastern shores of the Adriatic.* Foreign ships, therefore, are

* We are far from applying to those plans, and to their authors, those terms of indiscriminate censure which by many writers have been so abundantly directed to them. It is true that many, perhaps the great majority of them, were visionary, but their authors deserve at least the praise of endeavouring to do well, and of checking an alarming evil. What would have been our condition, had the public felt no interest in the welfare of its Navy, had the national spirit been so degraded, so morbid, and so dead, that it regarded neither the destruction of the natural bulwarks of the Country, nor the consequences to which so fearful a state of things must have led? This keen interest respecting our political state, and the maintenance of our national glory and honour, is surely an index of a healthy state of the public mind.

* It is remarkable that the Rivoli was built of oak which had been paid for by this Country, and brought down to the sea-coast at our expense to be shipped for England. The defection of Austria at this juncture put the French however into possession of it, the timber having been unfortunately placed in a most convenient situation for the use of their Naval Arsenal near Venice. Though the English paid for the timber, the French paid for putting it together and fitting out the ship.

The Rivoli was floated out of the harbour over the bar that crosses the passage about midway, by means of a camel or water-tight box, resembling those used at Amsterdam and St. Petersburgh. The departure of the ship was anxiously watched by Captain John Talbot, in the Victorious of 74 guns, and the Weazle brig of 18 guns, Captain Andrews. The English ships arrived off Venice on the 16th of March, 1812, and on the 21st got sight of the Rivoli. She was attended by a large ship, two brigs, and two

Naval Architecture.

as much subject to the inroads of dry rot as our own; and we may perhaps say, more so.

Other causes of decay. Marine animals attack the bottoms of ships.

(389.) Ships, however, are subject to other causes of decay, besides those already enumerated. Marine animals attack the planking in every vulnerable part, and sometimes occasion the most alarming evils. In some climates, particularly in the East and West Indies, on the coast of Africa, and in the Mediterranean, the destruction of timber is found to be much more rapid than in others, from the abundance of these animals infesting those seas. The danger to be apprehended from them there is very great; and indeed it is every where unsafe to allow any part of a ship's bottom to remain unprotected from their attacks.

Investigations of Mr. Willcox.

(390.) According to Mr. Willcox the most destructive of these marine animals are the Teredo, the Pholas, and the Lepisma. The former genus is most to be dreaded, and is said to have been originally imported from India It penetrates the hardest wood, and increases gradually in size as it proceeds in the work of destruction, until the part attacked by it frequently becomes like a honeycomb. It is but rarely that they bore through, although they frequently approach the inner surface within a very short distance, leaving a substance not thicker than the twentieth of an inch from the inside.

Extreme danger from the attacks of these animals.

There is an instance connected with the Sceptre of 74 guns, which fully proves the extreme danger of their attacks. This vessel left Bombay for England in 1807, and after being some time on her passage, was obliged to return in consequence of a serious leak proceeding from her bow. On examining her, it was found to have resulted from some of the copper having been rubbed off, and the parts of the bottom and the gripe thereby exposed being attacked by the Teredo, which had penetrated these places to so great an extent as to render her quite unsafe to pursue her voyage, without putting on new planks on the bottom, and shifting the gripe. The species of Teredo most commonly found in ship's bottoms is the *Teredo Navalis*.

gun-boats steering towards the port of Rota, in Istria. The Victorious and Weazle gave chase, and at a quarter past four in the morning, the Weazle being a head, brought the two brigs to action. At five, the Victorious being within pistol-shot of the Rivoli, a furious action began. Soon after, one of the enemy's brigs blew up, and at daylight, Captain Talbot saw the Weazle in chase of the other, but recalled her, perceiving she did not gain upon the enemy. The other ships and the gun-boats were not in sight, and the contending ships being in seven fathoms water, off the Point of Grao, Captain Talbot thought the brig would be of more service near him, in case of either ship getting on shore. Captain Andrews placed his brig within pistol shot on the bow of the Rivoli and gave her three broadsides. It was now nearly calm, and the action had lasted four hours. The fire of the enemy was very faint, and at a quarter before nine she surrendered. She bore the broad pendant of Commodore Barré, the Commander-in-chief of the enemy's force in the Adriatic.

At no period of the action were the two line of battle ships at a greater distance than half musket shot from each other. The Commodore did not surrender until nearly two hours after his ship had become unmanageable. His mizen mast fell just before he struck his colours, when his captain, most of his officers, and 400 of his men were killed or wounded. The loss on board the Victorious also was very great. She had 42 men killed and 99 wounded. The Rivoli had on board 892 men at the commencement of the action, but the Victorious no more than 512, of whom 60 were in the sick list. Captain Talbot received a medal for this action, and, subsequently, was made a Knight of the Bath. Captain Andrews was made Post, and Lieutenant Peake of the Victorious a Commander. It is a curious fact, that after the valuation of the Rivoli, no less a sum than £13,000 was deducted from the proceeds for damages done to the ship in action.—Brenton, *Naval History*.

Thus though we at first lost the *timber* which had been paid for by British money, by the defection of Austria from the common cause, the gallantry of British sailors added the ship which had been *constructed* with French money to the Navy of England, with a large share of glory in addition.

On the Tonnage of Ships.

Tonnage. Origin of the present erroneous rule.

(391.) The rule commonly employed for finding the tonnage of ships is open to the most formidable objections. Founded on error, it opens a door to deception and fraud, and even the good qualities of merchant ships have been sacrificed to the desire of obtaining excessive ladings, which this rule largely encourages. It owes its origin to the 13 Geo. III. cap. 74, which declares that "the length shall be taken in a straight line along the rabbet of the keel of the ship; from the back of the main stern post to a perpendicular line from the fore part of the main step under the bowsprit. The breadth, also, shall be taken from the outside of the outside plank, in the broadest part of the ship, either above or below the main wales, exclusive of all manner of doubling planks that may be wrought upon the sides of the ship." In cases in which it may be necessary to ascertain the tonnage of vessels afloat, it was further declared by 26 Geo. III. cap. 60, that to obtain the length, the measurer is to "drop a plumb line over the stern of the ship, and measure the distance between such line and the after part of the stern post, at the loadwater mark; then measure from the top of the said plumb line in a parallel direction with the water, to a perpendicular point immediately over the loadwater mark, at the fore part of the main stem, subtracting from such admeasurement the above distance; the remainder will be the ship's extreme length, from which is to be deducted three inches for every foot of the load draft of water for the rake abaft." Then by 13 Geo. III. cap. 74, and 26 Geo. III. cap. 60, "from the length taken in either of the ways above mentioned, subtract three-fifths of the breadth taken as above, the remainder is esteemed the just length of the keel to find the tonnage; then multiply this length by the breadth, and that product by half the breadth, and dividing by 94, the quotient is deemed the true contents of the lading."*

Algebraic expression of this rule.

(392.) This rule expressed in algebraic language,—the only language in which rules should at any time be delivered, is

$$\frac{L \times B \times \dfrac{B}{2}}{94} = \frac{L \times \dfrac{B^2}{2}}{94},$$

where L represents the length, and B the breadth.

(393.) By this rule the whole of the vast tonnage of the British Naval and Commercial Marine is computed. Instances without number might be given of the errors

* According to Mr. Parsons, the origin of this rule is as follows: A body floating in a fluid displaces a volume of that fluid, the weight of which is equal to the whole weight of the floating body. This displacement must always bear some relation to the principal dimensions of a ship, denoted here by L, B, and D. It has been found, that in vessels of rather full forms, the displacement estimated in cubic feet of sea water, is equal to sixty two-hundredths of the product of these three dimensions; which being divided by 35, the number of cubic feet of salt water in a ton, will give

$$\frac{L \times B \times D \times .62}{35}$$

for the displacement in tons.

The draught of men of war is generally about half the extreme

it occasions. Even by calculating the tonnage of the same vessel by the two methods above given, the results will be very different. Thus if we take the cutter given by Mr. Parsons in his *Scales of Displacement of the British Navy*, and apply the first method, the length to be taken will be 52.25 feet, and the tonnage 160 tons; but if measured by the second method, which involves the length of the water line, and is here found to be 50.4 feet, the tonnage will amount only to 154 tons. If, moreover, the rake of the stern post be increased, and the rake of the stern diminished, the water line remaining unaltered, the length by the keel will be only 48.5 feet, and the tonnage 148 tons. And supposing on the contrary the rake of the stern post to be diminished, and the rake of the stern increased, the length by the keel will then be 58 feet, and the tonnage 177 tons. But all the cases when measured afloat, or by the water line, will give a tonnage of 154 tons. Thus in so small a vessel as a cutter, a variation of 29 tons may be made in the register of the vessel, without any sensible difference in its real capacity, while the absolute weight this vessel can carry under all the above circumstances amounts only to 90 tons.

Instance of its errors.

(394.) In like manner the length of the keel may be constant, and the water line vary, by altering the rake of the stern and stern post. Even the form of the head of the rudder will alter the tonnage of a vessel; for if a round headed rudder be substituted for one of a square headed form, the back part of the post being taken off to receive the round head, the water line becomes immediately shortened, and the tonnage, as a necessary consequence, diminished.

(395.) It has been observed, also, that by omitting the draught of water in the rule, the practice of increasing the depth has become general, by which means vessels are capable of carrying a greater burthen without increasing the tonnage;* nor is this the only defect, a far greater one existing by omitting to take the form of the vessel into consideration. This error in the rule operates to such an extent at the present time, as to make the register tonnage of merchant vessels amount generally to two-thirds only their absolute burden. This excess of the absolute burden above the register tonnage, results entirely from the form, and is found to vary in almost every vessel, even where the principal dimensions are the same; and as the present rule for tonnage is entirely independent of the form of the vessel, the excess is entirely exempt from dues. Should the dues be laid on the apparent tonnage, with reference to this excess, the objection will not be removed, since the excess is not constant. The register tonnage of men of war is considerably greater than their absolute burden.

How the rule may be evaded.

(396.) These, and similar methods, open a boundless scope for evasion and fraud, according to the peculiar views of the builder or owner of the ship. This is, at once, a sufficient reason why the rule should be improved; for where can be the wisdom of that legislation which opens a door to dissimulation and deceit in any form?

Method employed by the French.

(397.) Different nations employ different rules for the admeasurement of tonnage. The French add the length of the deck taken between the rabbets to that of the straight line of the keel, and take half their sum. This quantity is multiplied by the greatest breadth at the midship beam, and that product by the depth of hold and height between the lower and upper decks, the whole product being divided by 94. If the vessel has only one deck, the greatest length of the vessel is multiplied by the greatest breadth in midships, and that product by the greatest height, the whole being divided by 94. This rule is simple, but very erroneous. A certain depth of the vessel is taken as a third dimension, but it is altogether independent of the immersion produced by the lading, *viz.* the depth from the load to the light water line, and which is most essential to be considered. This depth, it is evident, may vary very considerably in two vessels whose ladings are the same. One may be much deeper than the other, from a greater rise of floor, the total displacements of the two vessels remaining the same; and this depth may also vary from the decks being placed at different heights in the two vessels. The different forms of body are also totally neglected in this method of measurement.

Method of the Chinese.

(398.) The Chinese take only two dimensions for finding the tonnage of ships, the length from the centre of the mizen mast to the centre of the fore mast, and the extreme breadth close behind the main mast. These dimensions are multiplied together, and the result divided by 10 gives the tonnage. This method of measuring shipping for the purpose of charging duty is very favourable to large ships.

Method of the Americans.

(399.) For measuring the tonnage of merchant ships in the United States of America, the 64th section of an Act of Congress, approved March 2, 1799, declared, "That to ascertain the tonnage of any ship or vessel, the surveyor, or such other person as may be appointed by the collector of the district to measure the same, shall, if the said ship or vessel be double-decked, take the length thereof from the fore part of the main stem, to the after part of the stern post, above the upper deck, the breadth thereof at the broadest part above the main wales, half of which breadth shall be accounted the depth of such vessel; and shall then deduct from the length three-fifths of the breadth, multiply the remainder by the breadth, and the product by the depth, and shall divide this last product by 95, the quotient whereof shall be deemed the true contents or tonnage of such ship or vessel.

breadth of the ship, and at the time of the formation of the rule, the same relation probably existed in merchant ships. If, therefore, $\frac{B}{2}$ be substituted for D, the preceding expression will become

$$\frac{L \times \frac{B^2}{2} \times .62}{35};$$

and as the weight of the hull, stores, &c., was generally about two-fifths of the whole weight, leaving three-fifths for the weight of the cargo, we shall further obtain

$$\frac{L \times \frac{B^2}{2} \times .62}{35} \times \frac{3}{5} = \frac{L \times \frac{B^2}{2}}{94},$$

for the burthen in tons, which is the common rule.

* It is a curious fact, that a ship, which, in the port of London, was put into dock for the purpose of being raised upon, so as to increase the capacity of stowage, before going into dock, admeasured more than *after she had been raised upon*, although by the alteration she acquired the capacity of carrying nearly 100 tons more than she could have done previously to such alteration. On re-survey, she measured *less* when she came out of dock, than under her old register, although 100 tons larger. The ship in being raised upon was rather *narrowed* in her width; the consequence of which was, that the increased depth of hold not being included in the calculation of her tonnage, she became less in tonnage by admeasurement to what she was at the time of the original register being granted. *Edinburgh Review*, No. 90. p. 456.

Naval Architecture.

And if such ship or vessel be single-decked, the said surveyor, or other person, shall take the length and breadth as above directed, in respect to a double-decked ship or vessel; shall deduct from the said length three-fifths of the breadth, and taking the depth from the under side of the deck-plank to the ceiling in the hold, shall multiply and divide as aforesaid; and the quotient shall be deemed the tonnage of such ship or vessel."

(400.) These rules appear to have been derived from the English and French rules: the first, for double-decked vessels, being nearly the same as the English, and the latter, for single-decked vessels, being nearly the same as the French. They respectively possess the inaccuracies of each, with the additional error of being inconsistent with each other.

Swedish rule.

(401.) In 1778 the Swedish government adopted the following rule:

"1. All mensuration is to be done by the Swedish foot, and the vessel's burden is to be marked down in lasts, each to be considered in weight equal to 18 skeppund, iron weight, or eighteen times 320 pounds Swedish. 2. The vessel's length is to be measured on the highest water line, when loaded, from the fore part of the rabbet of the stem to the aft part of the rabbet of the stern post. 3. The ship's breadth is to be measured in midships without board, close up to the main wale. 4. The height is to be measured from the surface of the water without board, up to that mark which determines how deeply the vessel will swim when completely loaded. 5. These three admeasurements are to be multiplied together, and the product divided by 112, should the vessel be of the usual shape, and neither too full nor too sharp at the stem and stern. If the vessel is sharper, the divisor must then be greater, and if fuller a little less, as pointed out to the measurer in the separate instructions. 6. If the necessary provision, water, wood, and utensils for the voyage be not on board when the ship is measured, and which weight does not actually belong to the burden the vessel is measured to carry, it is then necessary to deduct from the calculated burden of lasts as follows:—on a vessel of 350 lasts is allowed 11 lasts deduction; (corresponding deductions are given for vessels decreasing in burden from 350 to 40 lasts;) and so on in proportion, in such vessels as are not coincident with the above denomination. But should any of the articles mentioned be on board, the deduction will be less in proportion. 7. Should one or more of the necessary cables not be on board when the vessel is measured, the following deductions are to be made: for an 18-inch cable 25 skeppund, iron weight. (The deductions for smaller cables, down to a four-inch cable, are specified.) 8. Should one or more anchors be wanting, their weight is to be deducted in proportion to the vessel's size. 9. If the vessel's sails are not on board, the deduction from its number of lasts is to be as follows: on a vessel of 350 lasts, 14 skeppund, iron weight. (Corresponding deductions for the sails of smaller vessels, down to those of 40 lasts, are given.) And less in proportion when fewer sails are wanting. 10. If the vessel is built to carry guns constantly, and that none, or part of them only, are on board, a deduction for cannon, carriages, gun-tackling, &c. is to be made as follows: for a 12-pounder, with its requisites, 13 skeppund, iron weight (with corresponding deductions for smaller guns.) 11. Should the vessel, when measured, have its ballast on board, then that weight must be ascertained, and added to the number of lasts found; but it is best to measure the vessel before it is ballasted, if convenient. 12. The ship's measurer having duly considered the foregoing circumstances, and in consequence thereof ascertained the vessel's proper tonnage to a certain depth, fore and aft, when loaded, he is then to make an entry of the foregoing in the book of admeasurements given him for that purpose, which book is run through and sealed with the seals of the Court of Aldermen and Custom House: he is also to enter the number of lasts requisite to immerse the vessel, progressively, from one foot at the beginning of the loading till when completed, and also to set down how deep she lies fore and aft when unloaded. He is to deliver copies of the same, with specific calculations, admeasurements, and deductions of all this, to the Court of Aldermen and Board of Customs, within two days after measured, that the same may be examined and sanctioned. 13. Should there be any thing to be observed by the parties, the same must be made known at the respective places, within eight days after the delivery, at the expiration of which time the ship's register will be made out, and the approved calculation of the measurer annexed to the same, and to be kept on board as the ship's inventory. The same is to be entered, with all the calculations, in bound paged books, and alphabets thereunto annexed, in the Court of Aldermen and at the Custom House. 14. Whereas vessels, when old, and soaked through by the water, cannot carry so much as when new, it is therefore requisite to measure the vessel every tenth year, in like manner as expressed in the twelfth section."

Divisions into seven classes.

(402.) In the instructions alluded to in the fifth section, vessels are supposed to be divided into seven classes, according to their fulness or sharpness; and corresponding divisors are given, obtained by calculations from different vessels. These divisors vary for the whole depth immersed by the lading, from 104 for the fullest, to 122 for the sharpest vessel; and the divisors to be used near the load water line vary from 98 to 104, and near the light water line, or discharging line, from 108 to 133.

(403.) Mr. Morgan remarks on this rule, that it is strictly correct in principle, and that the only error which can arise in practice, is in the divisor being left to the determination of the measurer. A skilful measurer, after great practice, will be able to determine the divisor with ease and certainty.

Rules of Mr. Parkin.

(404.) Mr. Parkin has given two rules for calculating the tonnage of ships, published in *The Shipwright's Vade Mecum:* one for ships of the Royal Navy, and the other for merchant ships. The following is his rule for merchant ships:—1. "Find the length of the lower deck, from the rabbet of the stem to the rabbet of the stern post, and take $\frac{1}{1}\frac{1}{2}$ of this length for the *keel for tonnage.* 2. To the extreme breadth add the length of the lower deck, and take $\frac{1}{35}$ of this sum for the *depth for tonnage.* 3. Set up this depth from the limber strake, and at that height take a breadth also from out to out of the plank at dead flat. Take two more breadths, one at two-thirds, and the other at one-third of the height. Add the extreme breadth and these three breadths together, and take one-fourth of the sum for the *breadth for tonnage.* 4. Multiply the length, depth, and breadth for tonnage continually together, and divide the resulting product by $36\frac{2}{3}$, which will give the burden in tons." This rule seems to make a little approach towards the true measure-

ment of tonnage, but it is not founded on correct principles.

Chapman's rules.

(405.) In 1792 Chapman furnished two rules on this important subject. The first was an approximate rule, relating to the payment for the building of ships. "The cost of a ship," he says, "is nearly in proportion to its outer surface multiplied by the thickness of its sides; but as this thickness may be considered in proportion to one of the dimensions, so it may be judged that the product of the length, breadth, and depth gives the proportional costs. A difficulty, nevertheless, attends this, because the length and breadth can be precisely fixed, but the height or depth cannot. For instance, if the depth of the hold be used as the third dimension, it may happen, in consequence of the cargo which the vessel is to carry, that the lower deck has been laid a foot higher or lower, although its length, breadth, and the whole of the height remain the same; the expense of building, as also the burden, remain the same; but the difference of the height of the deck increases or decreases the product, and consequently the cost in proportion. The same thing takes place with regard to the upper deck. Should the height of the vessel from the keelson to the gunwale be taken as the third dimension, it will be found to vary just as much as the former. For example, the gunwale might be made half a foot or a foot less in height, and this quantity added to the gunwale after the ship is built, which of course would make it cost less than if that height was included in the calculation. If that part of a ship which is immersed when loaded should be taken as the third dimension, the question to be considered would be how high the water line stands marked on the draught up to which the ship ought to be loaded, which might also be higher or lower. It is, therefore, better to institute a rule which, although not totally exact, is still not subject to disputes or confusion.

"I therefore propose," says Chapman, "that the ship's height or depth should be taken so as to bear a proportion to two dimensions, namely, as the square root of the product of the length and breadth. If now the length and breadth be expressed by L and B, then must the depth bear a certain relation to $\overline{LB}|^{\frac{1}{2}}$, without regarding how great that quantity may be. This multiplied by the length and breadth, the number of tons will be proportional to $\overline{LB}|^{\frac{3}{2}}$. This expression represents the solidity, and in which two of the principal dimensions are equally involved. To apply it to the determination of a ship's burden, it will be necessary to find what proportion the breadth bears to the length, agreeably to the old method of determining the tonnage when the contract has been equally beneficial. Suppose the breadth to have been $\frac{53}{200}$ of the length, or the length to be 100 feet when the breadth is $26\frac{1}{2}$ feet. According to the old method,

$$\frac{\left(100 - \frac{29}{40} \times 26.5\right) \times \frac{26.5^2}{2}}{94} = 301.78 \text{ tons};$$

whence

$$\frac{(100 \times 26.5)^{\frac{3}{2}}}{x} = 301.78, \text{ and } x = 452.$$

Hence the tonnage of a ship ought always to be expressed by $\frac{\overline{LB}|^{\frac{3}{2}}}{452}$."

This divisor, 452, is subject to alteration according to circumstances.

(406.) Chapman's other rule is for the correct determination of the weight of the lading a ship carries. This rule is similar to that given by the Swedish Government, except that the divisors are adapted to the English ton, instead of the Swedish skippund. He gives a table for ten classes of vessels according to the fulness or sharpness of their bodies, in which the divisors vary from 39 in the fullest, to 48 in the sharpest vessel. He takes the extreme length on the load water line L, the extreme breadth just below the main wale B, and the mean depth between the light and load water lines. The product of these three dimensions, divided by D, the variable divisor in his table, gives the lading in tons.

Another rule.

(407.) A rule for the measurement of tonnage has been given which approximates nearly to the true weight of lading, by multiplying together the length of the load water line between the fore part of the rabbet of the stem and the after part of the rabbet of the stern post, the greatest breadth, and the mean depth between the light and load water lines; taking three-fourths of the product, and dividing by 35. To this sum is added an allowance in proportion to the fulness of different bodies, determined by actual measurement.

Another example of the error of the common rule.

(408.) In the *Shipwrights' Repository* the error of the rule commonly employed is clearly explained, and the true tonnage shown to be the difference between the total weight of the ship to the load water line, and the weight of the hull and furniture. The author has given several examples of the tonnage of ships: the following is the result of his calculations of the tonnage of an 80-gun ship:

	Tons.	lbs.
Weight of the ship at her launching draught of water	1593	406
Weight of the furniture	195	720
Weight of the ship at her light water mark	1788	1126
Weight of the ship at her load water mark	3554	356
From which deduct the weight at light water mark	1788	1126
Real burden	1765	1470
Burden in tons by common rule ...	1959	929
Real burden	1785	1470
Error....	193	1699

(409.) The real burden of this ship is therefore 193 tons less than her computed tonnage. In an East Indiaman, his result shows that the real burden was 178 tons more than her computed tonnage. In other examples the differences are still greater.

(410.) Chapman, Clairbois, Atwood, and latterly Mr. Parsons, have calculated and drawn scales of tonnage for particular ships. The latter has made the calculations and drawn the scales of tonnage, for most of the classes of ships of his Majesty's Navy, and for twenty-one classes of vessels of the British mercantile Navy.

Mr. Parsons's labours on this subject.

(411.) Mr. Parsons's scales of tonnage are drawn for all these vessels from the keel to the gunwale. Each vessel is divided into fore and after bodies, by a vertical line proceeding from the middle of the length of the

Naval Architecture. Scale of tonnage.

load water line, between the fore side of the rabbet of the stem and the aft side of the rabbet of the sternpost; and a separate line of tonnage is drawn for each body. The solid content of the body in cubic feet, at different heights, is calculated by sections parallel to the keel, which being divided by 35, the number of cubic feet of sea-water in a ton, gives the weight of water which would be displaced at those heights. By setting off from a vertical line, on lines parallel to the keel, these results by a scale of tons, spots are obtained, through which the line of tonnage may be drawn. By setting up, moreover, any height on the vertical scale of feet, and drawing a horizontal line at that height, it will represent the weight of the corresponding displacement, and which is found by transferring it to a scale of tons placed horizontally over the figure. By taking, also, the heights of the light and load water lines of any vessel, and transferring them in this manner to the scales of tonnage, their difference will give the weight of the displacement between the light and load water lines, or the true weight of lading. The mean depths are taken for each body separately, and the sum of the two parts thus found gives the total tonnage.

(412.) By these lines of tonnage may be ascertained the weight put on board, or taken out of a vessel at any time, by observing the different draughts of water, and measuring the tonnage or weights corresponding to them. The difference of these weights will be the quantity put into or taken out of the vessel. For example, in a cutter of 160 tons, when ready for sea with all her stores, the draught of water is 8 feet 9 inches forward, and 13 feet 6 inches aft, the mean being 11 feet 1½ inches. The mean depth, also, for the after body is 12 feet 3¾ inches, giving 93 tons for its weight. The mean depth for the fore body is 9 feet 11¼ inches, giving 83 tons for the weight of that body, making the whole displacement 176 tons. The weight of the hull when launched having been 82 tons, the difference on the weight put on board must be 94 tons.

(413.) This method of taking the mean depth in each body, though most correct, will seldom be necessary, because if the mean depth of the extremities be used alone for each body, it will give nearly the same result. The tonnage is then measured by taking the mean depths of each body separately, and the difference of the results of the two methods is found to be only one ton. In vessels having a less difference of draught of water, the error is proportionally less. On this account, the mean depths of the load and light draughts of water are used in the scales of tonnage, which supposes the vessel to swim on an even keel, at the mean draught of water in each case.

Remarks.

(414.) In considering the practical benefit of the scales of tonnage, observes Mr. Morgan, it is necessary to examine the difficulties which would attend their application. This method of measuring the tonnage of ships is strictly correct, assuming the light and load draughts of water to be known; but it is in the practical determination of these lines that the difficulty exists. Mr. Parsons has assumed the launching draught of water as the light draught; and this is the easiest method, but not the most correct. The tonnage should express the lading which can be put into a ship, when every necessary article of furniture and stores is on board, in order to bring her down to its load draught of water. The two Swedish methods given above removes this difficulty, by taking the light draught of water, when every thing is on board except the lading; an established allowance being made for every article not on board at the time. This method may be attended with trouble, in obtaining the weights of the different furniture and stores; but it is the only mode of determining the correct light draught of water, which is the first element necessary in measuring a ship's tonnage. The next difficulty, and by far the greatest, is the determination of the load draught of water. Two methods suggest themselves of accomplishing it. It may be determined by officers appointed for the purpose, the moment a ship is built, and the result inserted in the register, by which draught of water the tonnage may be measured. The objections to this method are, the liability of the load draught of water being incorrectly determined either by fraud or ignorance, and afterwards requiring alteration; and the opportunity it affords the owner of taking on board, at his own risk, a greater lading than that for which his ship was registered. Experience may, however, render the officers capable of ascertaining the load draught of water with considerable accuracy, and fines may deter the owner from incurring the risk of loading his ship deeper than it was constructed to swim with safety. Another method of obviating the difficulty, is by a ship's always paying duty on the quantity of lading on board; so that the measurement of tonnage may be taken at the actual draught of water at which the ship swims when it comes into port. This would render the load water line at first determined little more than nominal: it would allow a vessel's being spoken of as having a nominal tonnage, producing no error in the measurement of the real tonnage on board. Either method will render these scales of tonnage applicable to general use; but the latter may be preferred, because it brings the correct principle of measuring the true lading fully into practice.

Naval Architecture.

(415.) It is probable that tables of tonnage may be preferred by many to scales of tonnage; but as their principle and use would be the same, the preference is indifferent. It may, also, be observed, that if the whole displacement were represented by one scale, instead of being divided into two parts for the fore and after bodies, the use of these scales would be more simple in their application to the tonnage of ships, although less useful for general purposes of design.

(416.) Mr. Parsons has applied scales of the exterior surfaces founded on the dimensions, scantlings, &c. of ships to the determination of their charges for building. Any surface of this kind multiplied by the mean thickness of the ship's side, would give a tolerably correct measurement of the quantity of materials. As the expense of building vessels must be in proportion to their outside surfaces, these lines will be a much better criterion for estimating the expense than the register tonnage.

Example of Mr. Parsons's mode

(417.) Fig. 10. pl. ii. is an example of Mr. Parsons's mode of finding the tonnage of a brig of 170 tons, register tonnage. Suppose this vessel to have every thing on board except the cargo, and her draught of water to be six feet at the stem and sternpost, or on an even keel. Set this distance up from the base line, or lower side of the false keel, and draw the line A 12 parallel to the base, intersecting the line of tonnage 1 for the after body in B. Then will the distance A B applied to the scale, measure 46 tons, the weight of the after body. The same line intersects the line of tonnage 2 for the fore body in C, giving for A C 64 tons, the

weight of the fore body. The whole weight of the vessel with every thing on board, excepting the cargo, is therefore 110 tons. Suppose now the cargo to be put on board, and the draught of water 12 feet at the stem and stern post. At 12 feet from the base draw D 11, which will give for the corresponding weight of the after body 157 tons, and for the fore body 193 tons, giving for the whole weight 350 tons. The weight before the cargo was put on board having been 110 tons, the weight of the cargo itself must be 240 tons. When there is a considerable difference in the draught of water at the stem and sternpost, Mr. Parsons recommends the medium depth to be taken for each body, instead of the depth in the middle of the vessel.

Other properties of the figure.

(418.) The other lines in the figure have some useful properties. That marked 3, for example, denotes the whole area of the horizontal sections in square feet of the after body, and that marked 4 in the same manner for the fore body. The line denoted by 5 represents the whole exterior surface of one side of the vessel, in square feet, of the after body, and the line 6 of the fore body. The line 7 is for the whole area of the vertical sections, as high as the load water sections, in square feet, of the after body, and the line 8 for the fore body. ⊕⊕ gives the situation and form of the principal transverse section; 9, 9 the situation and form of the section in the after body, whose area is equal to two-thirds the area of the principal section, and 10, 10 in the fore body. 11 and 12 represent the load and light water lines. An analytical investigation of the properties of these singular curves would be likely to lead to some useful and important results.

Present rules operate against improvement of mercantile marine.

(419.) The facility which the ordinary rules for finding the tonnage affords for the evasion of dues is not the only evil attending it. It unfortunately operates against any improvement in our mercantile marine. Great capacity with small dimensions is now the primary object of consideration; and this is too often obtained by sacrificing expedition and safety. If the tonnage gave a true measure of the capacity of the ship, there would be no cause why the mercantile Navy should not equal, or indeed excel, the military in every quality of safety and velocity; whereas it is a well-known fact, that the British merchant shipping is inferior to that of almost every trading Country in the World.

Labours of Society for Improvement of Naval Architecture.

(420.) Attempts have not been wanting to improve these imperfect modes of determining the tonnage, but hitherto without success. In 1791 the Society for the Improvement of Naval Architecture offered a premium of twenty guineas, and a silver medal, for the most ready and accurate method, by approximation or otherwise, for determining the tonnage of vessels and ships of every description, from an admeasurement of all the principal dimensions. The two rules of Chapman, before adverted to, were given in consequence of this invitation.

Report of a Committee in 1821. Another appointed in 1832.

(421.) On the 24th of May 1821, a Report of a Committee consisting of several distinguished Members, was delivered to the Admiralty, and in 1832 another Committee was formed with the view of improving the subject. Of the various plans that have been submitted to them, it has been said some are too laborious and complicated for general practice, and others entirely erroneous. Mr. Parsons's Tables seem to form a distinguished feature among these investigations. In a communication made from the Board of Trade to Mr. Lushington, at the time that gentleman was one of the Secretaries of the Treasury, it was urged, that if any new method should augment the tonnage duty, the proprietors should not be subject to additional burthens. It is singular that among the many minds occupied with this useful and important practical question, no one has yet been able to devise a short, accurate, and convenient rule. The object in all these attempts should be, not so much to diminish the present error, as to abolish it entirely. Simplicity is most desirable, but considering the varied forms that ships' bodies put on, it should not be obtained by a sacrifice of principle. We confess we look to the scale of tonnage as one of the great means by which this useful end will be accomplished.*

Seppings's Rules for building and rebuilding Ships of the Line, Fifty-gun Ships on two Decks, and Frigates.

Seppings's rules for building ships of the line, &c.

(422.) Accurate and precise rules for the practical operations of ship-building are of the greatest importance to the successful prosecution of the Art. In vain might the most perfect theories, *did we possess them*, devise forms possessing stability, stowage, and velocity, if, when the fabric is to be reared on the slip, weak and inefficient combinations of timber are to be employed in its formation. A knowledge of scientific carpentry—of the best modes of combining timber, so as to unite a maximum of strength with a minimum of material—is possessed but by very few Naval Architects. Thousands of loads of timber were annually consumed in ship-building, yet, before the time of Seppings, where were the successful instances to be met with of timbers exerting all their power, and disposed according to principles which the eye of Science delights to contemplate? The praise of Seppings is, that he accomplished all this and more for Naval Architecture; and that he imparted to our great and splendid marine a degree of mechanical strength it never possessed before.

Frame agreeably to the common disposition.

(423.) In the common disposition, all the timbers are to be framed together in bends, (except the short timbers over the ports,) each scarf to be bolted with three bolts of $1\frac{1}{8}$ inch diameter for ships of the line, and one inch for 50-gun ships and frigates. The first futtocks also to be bolted to their respective floors, with three bolts in each scarf of $1\frac{1}{4}$ inch diameter for ships of the line, and $1\frac{1}{8}$ inch for 50-gun ships and frigates. The filling frames under the ports to be so opened as to divide the space equally.

(424.) The greatest attention must be paid that the lips of the chocks at the heads and heels of the timbers be at least three inches in thickness, for ships of the line, and not less than $2\frac{1}{2}$ inches for 50-gun ships and frigates, and that the abutments for the lips be cut on the timbers as near to a square as the faying of the chock will admit.

(425.) The chocks are to be roughly trimmed with a sufficiency of overcast, and placed with their faying sides outwards in their respective situations, in which state they are to remain during the seasoning of the frame. Each range of chocks is to be placed on a small fore and aft riband, which is to be kept from coming in contact with the timbers by fitting a piece of

* Since this was written the Committee has published a short Paper on the methods at present in use for measuring tonnage. It may be seen in the *United Service Journal* for June 1834.

batten for every nail to pass through. Such chocks as may be converted from free grown timber, and are therefore liable to split in the course of seasoning, are to have a small treenail driven in a direction from a right angle about nine inches from each end.

(426.) When the chocks are refayed and replaced after seasoning, the faying parts of both chocks and timbers are to be well fayed with oil and tar.

(427.) The heads and heels of the timbers are to be scarfed where so directed on the disposition of the frame, but the heads and heels of all other timbers, where the conversion will admit, are to be wrought square, painted at each end with white lead, and put together with a circular coak in each joint, of a diameter about one-third of the siding of the respective timbers. In the event of the timber being partially shifted so as not to admit of introducing the coak, a bill is to be substituted, which is to be formed on the lower timber to prevent a lodgement of water; such timbers as cannot be procured with square heads and heels are to be scarfed.

(428.) All the timbers are to be framed together in bends, and to be bolted with two bolts in each scarf of $1\frac{1}{8}$ inch diameter for ships of the line, and one inch for 50-gun ships and frigates, and the lower scarfs with bolts of $1\frac{1}{4}$ inch for ships of the line, and $1\frac{1}{8}$ inch for 50-gun ships and frigates.

(429.) The under side of the wing transom to be sided straight and laid at a right angle with the rabbet of the post, and to be sided as much as the piece will admit. If the store will not supply a piece of timber of sufficient dimensions to make the wing transom for a large ship, it may be formed with four pieces. No transoms are to be introduced below the wing transom, but that part of the ship's frame is to be formed with timbers as described in the drawings. Ships built on this principle are to be single fastened throughout.

(430.) That the openings may be kept as clear as possible during the seasoning of the frame, the timbers are to be separated with wedges driven alternately, which are to be taken out as soon as the frames are put together; but in such cases where it may be absolutely necessary to introduce chocks in the usual manner, they are to be split out when the bolts shall have been driven.

Openings between the timbers of the frame to be filled

(431.) The openings between the frames are to be filled in and calked within and without board, from the keel to within four inches of the lower strake under the orlop clamps for ships of the line and 50-gun ships, and to within the same distance of the strake on the ends of the orlop beams in frigates. Care is to be taken that the outer edge of the upper filling lie rather above a level, by which means should any water pass between the timbers, it will be conveyed into the hold of the ship. Openings more than three inches are to be filled in with slab plank free from sap wood, or with sound old oak timber, with the grain in the same direction as that of the frame timbers, which fillings are to be so trimmed as to admit of wedge fillings on one side. Openings less than three inches are to be filled in with wedge fillings, driven in alternately from within and without side, and square with the curve of the body. The filling in is to be executed as the planking of the bottom is carried down, and as the ribands and harpins are removed.

(432.) All the fillings are to be provided as early as possible from offal and slab timber, free from sap, or sound old oak, and when trimmed, are, with the sides of the frame, to be well payed with oil and tar.

Dubbing off the inside of the frame.

(433.) The inside of the ship, below the orlop clamps, need not be dubbed off with that strict attention as if it were to be planked over, but to be made moderately fair, removing the projecting parts so as to prevent the lodgement of dirt.

(434.) The heads of the stem and stern posts and timbers under the ports must be well saturated with oil and tar during the seasoning of the ship, which may be done by making the heads of the timbers concave, and boring holes therein; the holes are to be plugged up, and the timbers cut fair and painted with white lead before the port cills are let in

(435.) Great care is to be taken that no sap be suffered to remain on any part of the frame, and that no piece be put in to make good the deficiency occasioned by its removal from the edges of the timbers until the fillings, &c., shall have been calked.

Calking the frame.

(436.) One joint of the fillings in each opening between the timbers of the frame, and also the joints of the frames in wake of the said fillings, are to be well raimed and calked both within and without board.

(437.) Great care is also to be taken that the oakum which may be driven from one side be brought into close contact with that driven from the other side, so that on no account whatever is any space to be left between the two calkings. When the raiming and calking as already directed shall have been performed, all the remaining joints of the fillings, butts of chocks, butts of timbers, &c. are to be chinced.

(438.) In fig. 1. pl. v. the method of filling in the openings between the timbers, &c. may be seen, and to which the following references may be made. A, a close joint; B, an opening of less than three inches; C, an opening of more than three inches; D, D, D, wedge fillings, the grain being *in* and *out;* E, a common filling, the grain being *up and down;* F, F, F, F, F, F, joints which are to be raimed and calked.

(439.) The fillings in wake of the chain bolts are to be as few as possible, their moulding to be two inches less than the frame, thereby leaving one inch for air to pass between them and the inner and outer planking. They are to be raimed and calked within and without; and should any fillings be required in the wake of the knees, or any other place above the general filling in, the same mode is to be followed.

Projections to be discontinued at the channel wales, bows, &c.

(440.) No projection is to be left at the upper edge of the channel wales, but at the upper and lower edges of the sheer strake projections are to be permitted as usual. No projection whatever is to be allowed without board afore the second lower deck port from forward, and to obviate the additional weight that would arise in consequence, the main wales, &c., are to be thinned at the fore end one-third of their respective thickness, and to begin to taper off about ten feet from the fore end. To render the port lids (where the projections are omitted) as light as they otherwise would have been, the stops are to be cut out of the plank without going home to the port timbers; to accomplish which, the short stuff between the ports must of course be worked fair with the sides of the port timbers.

Coaking the main wales,

(441.) The main wales, black strake, and four upper strakes of diminishing stuff, the middle and channel wales and sheer strakes, are to be coaked to the timbers

of the frame with reference to every butt as described in fig. 2.

Clamps, &c. for ships of the line.

(442.) The clamps and spirketing are also to be coaked to the timbers of the frame in a similar manner to the wales, &c., and the clamps are to be bolted with up and down bolts agreeably to fig. 3.

(443.) Where only one strake of spirketing is wrought, both butts are to be coaked to the timbers nearest their ends.

Coaking the main wales, clamps, &c. for 50-gun ships and frigates.

(444.) The main wales, sheer strakes, spirketing, and clamps, are to be coaked and bolted as directed for ships of the line.

Treenail fastening.

(445.) The timbers of the frame are to be single bored only, in wake of the water way, shelf pieces, and such other parts where fastenings driven for the security of the inside work are generally diffused; also the bottom of the ship where the inside planking is omitted, *viz.* from the lower edge of the plank next under the orlop clamps to the limber strake.

(446.) The general diffusion of metal fastenings introduced with the new system, together with the bolts for bringing to the plank, will more than compensate for the treenails left out.

(447.) Ships built upon the small timber system are to be single fastened throughout.

Orlop clamps for ships of three decks.

(448.) To have two strakes of orlop clamps on each side wrought top and butt, both eight inches thick, with two strakes on each side wrought under them, the upper strake to be six inches thick, and the lower strake four inches thick, which may also be wrought top and butt.

Orlop clamps for 80 and 74-gun ships.

(449.) Two strakes of seven inches thick wrought top and butt, with one of six inches, and one of four inches thick, wrought also top and butt under them.

(450.) Should there be any difficulty in procuring the middle shift of diagonal timbers for ships of the line, another strake (or two if required) of three inches thick, may be wrought in *midships* below the strake of four inches. Care is to be taken that it be not worked so low as not to give a five feet scarf to the middle rider from the upper part of the longitudinal piece at the first futtock heads.

Orlop clamps for 50-gun ships.

(451.) Two strakes of six inches thick, wrought top and butt, and one strake of four inches thick wrought under them.

Hold. Limber strake for ships of the line and 50-gun ships.

(452.) No plank or thick stuff whatever is to be wrought below the said strakes except one limber strake on each side, eight inches thick for ships of three decks, seven inches thick for 80 and 74-gun ships, and six inches thick for 50-gun ships, and to be coaked to the cross chocks only, with circular coaks, of 4½ inches diameter.

Limber strake for frigates.

(453.) No plank or thick stuff is to be wrought in this class of ships below the strake on the ends of the orlop beams, except one limber strake on each side of six inches thickness, which is to be coaked to the cross chocks only, with circular coaks of four inches diameter.

Additional keelson.

(454.) In the wake of the main mast an additional keelson is to be placed on each side, at such a distance from the common keelson that the ends of the step may rest upon it, to support the great pressure of that mast. The additional and regular keelsons to be coaked to the cross chocks only, instead of being faced down as heretofore.

(455.) To be of the same dimensions as the common keelson, and in length for ships of the line about twenty-eight feet, and for 50-gun ships and frigates about twenty-four feet.

Trussed frame.

(456.) Instead of thick stuff, plank, riders, &c., a trussed frame is to be introduced, the various parts of which (particularly the longitudinal pieces and trusses) are to be procured if possible from old ship timber, *viz.* the sound parts of old floors, first futtocks, &c. Should any sound old timber in a very dry state be made use of, it should be saturated with oil and painted with white lead to prevent an absorption of moisture.

Trussed frame for ships of the line.

(457.) The diagonal timbers for ships of three decks, the upper and lower ones to be fourteen inches sided in midships, and the middle ones fifteen inches; and for two-decked ships the upper and lower ones to be from thirteen to fourteen inches, but the middle ones are not to be less than fourteen inches sided. The fore and aft pieces at the floor heads are to be sided in midships from thirteen to fourteen inches as the conversion will admit, and afore and abaft from twelve to thirteen inches; the fore and aft pieces at the first futtock heads from eleven to twelve inches, the small dimensions to be used forward and aft.

(458.) The trusses to be sided from eleven to twelve inches, and with the fore and aft pieces to be moulded so as to conform to the diagonal timbers as nearly as the conversion will admit.

(459.) In executing the trussed frame the middle timber is to be first got into its station, and laid as nearly to a right angle from the body of the ship as possible; the upper part to abut against the fore and aft stuff that runs under the orlop clamps, and the lower part to be continued two feet six inches below the floor heads, or as much more as the piece will admit. The lower timber may next be placed, which is to abut against the limber strake, and to run at least two feet six inches above the floor heads, thereby giving a scarf of not less than five feet to the middle timber: and in order to take out the bevelling, or in other words to make the timber lie nearer at a right angle to the body, the lower end of the middle timber is to be reduced at the upper part, where it comes in contact with the lower timber. In the fore body it will be taken from the aft side, and in the after body on the fore side; the lower part of the upper timber, or upper part of the middle timber, is also to be taken away for the same purpose.

(460.) Should any difficulty occur in procuring compass timber for the diagonal frame, a saw kerf may be cut in the upper part of the upper, and in the lower part of the lower timber, thereby avoiding a kerf in wake of the scarf. This will render procuring these timbers less difficult.

(461.) In disposing of the diagonal timbers so as to clear as much as possible the chocks under the gun deck shelf piece, a chamfer of about six inches may be taken away when required from the angle of the lower edge of the orlop beam, as in fig. 4.

(462.) The scarfing of the diagonal timbers to be side by side, and each of the lower scarfs to be secured with two copper bolts of 1¼ inch diameter, and each of the upper scarfs with two copper bolts of 1⅛ inch diameter, which are to be driven square from the sides of the timbers.

(463.) Each shift or diagonal timber to be coaked to the frame timbers, and to the gun deck and orlop clamps with which they come in contact, with coaks of 3½ inches diameter, and 3½ inches in length.

(464.) The fore and aft pieces at the floor and first

futtock heads are to have their ends coaked to the diagonal timbers with coaks of four inches diameter, and of the same length. As these coaks must be double sunk either in the timber, or in the fore and aft pieces to ensure their being driven up, a piece of thin iron hoop is to be placed over one end of the coak to prevent its being split by the bolt in punching up; this precaution should be taken in all cases where coaks are double sunk.

(465.) Wherever there is a necessity of double sinking coaks, the vacant space is invariably and with the greatest care to be filled with a mixture of chalk and grease, or any other durable substance that can be introduced.

(466.) Great attention should be paid that the fore and aft pieces at the floor and first futtock heads be driven in tight between the diagonal timbers, and particularly the trusses, as they receive the weight of the ship when she has a tendency to arch or hog, and also when in the act of pitching.

(467.) As the trusses need not have any coaks at their ends, should they by accident be cut short, an iron wedge is to be driven at one end; and should they have shrunk, particularly at the upper ends, after they are put in place, thin iron plate wedges are to be driven in prior to the ship's being launched or undocked. In all cases a survey should be held to ascertain their state before the ships be launched or undocked.

(468.) The diagonal timbers are to be bolted with bolts of 1¼ inch diameter, the bolts to be from eighteen to twenty inches apart, except at the extreme ends, where two may be placed nearly abreast; and at the heads of those under the gun deck shelf piece, two bolts are to be driven through a plate of iron to secure them when the ship is in the act of rolling.

(469.) The fore and aft pieces at the floor and first futtock heads to be fastened at their ends with bolts of 1¼ inch diameter, and in the middle with bolts of 1⅛ inch diameter, and from twenty inches to two feet asunder, the ends excepted, where, as in the ends of the diagonal timbers, they are to be nearly abreast.

(470.) The trusses are to be secured with bolts of 1⅛ inch diameter, about two feet asunder. The upper trusses to be placed a little above a square or 90°.

(471.) In driving the bolts of the diagonal frame, all those in the ends, and one at least in the middle, are to be driven first, and from the inside, in order to draw the materials well in contact with the frame timbers.

(472.) Water courses are to be cut wherever there is a probability that water may lodge, particularly at the ends of the fore and aft pieces and trusses, also at the ends of the diagonal timbers that abut against the limber strake, and the keelsons in wake of the main mast; these water courses are to be formed by cutting off the angle with a plain chamfer at the upper part about four inches, and at the lower part five inches, the same to be observed with respect to the hooks, crutches, &c., but to a greater extent.

Trussed frame for 50-gun ships and frigates.

(473.) The materials for the diagonal frames of these classes of ships to be six inches thick. The timbers and fore and aft pieces to be from ten to eleven inches broad, and the trusses from nine to ten inches broad.

(474.) The upper range of timbers may be procured of small timber, sided eleven inches for 50-gun ships, and ten inches for frigates; the upper parts of which must be fayed to the clamps, &c., but the lower parts may be brought to with boiling in the kiln, should there be any difficulty of procuring timber of a proper growth.

(475.) Chocks of dry oak well oiled are to be wrought under the lower edge of the lower strake of inside stuff to prevent the scoring of the diagonal timber.

(476.) The other parts of the diagonal frame may be procured of thick stuff, and brought to with boiling, (should it be required,) excepting those parts afore and abaft to form the hooks and crutches, which may be converted from small timber sided from ten to eleven inches, and moulded as broad at the middle line as may be required to receive the iron plate hooks or crutches.

(477.) The bolts for the diagonal timbers to be in distance asunder from eighteen to twenty inches, except at the ends, where two are to be disposed of, as before directed for ships of the line; those for the upper range of timbers, and for the parts which form the hooks and crutches, are to be 1⅛ inch diameter, and the remainder one inch diameter.

(478.) Whenever the treenails of the bottom come in wake of, and at a *proper distance* from the edges of the fore and aft pieces and trusses, they are to pass through them; and the additional fastenings that may be required are to be made with bolts of ⅞ diameter; the ends are also to be secured with two bolts in each, as directed for ships of the line.

(479.) Water courses are to be formed by cutting off the lower angle of those parts of the diagonal frame which form the breast hooks and crutches; but *no water courses* are to be cut in any other part of the diagonal frame.

(480.) The greatest care is to be taken that the fore and aft pieces and trusses be driven in tight between the timbers, and that their butts be well compressed by raiming prior to their being calked. The upper trusses shall be placed a little above a square or 90°.

(481.) The hooks and crutches are to be constructed on a principle that will be shown by a drawing. Hooks and crutches.

	Line of Battle Ships. Cwt.	qr.	lbs.	Frigates. Cwt.	qr.	lbs.
Weight	5	1	14	4	1	7

(482.) The fore and aft carling under the after gun-deck beams, is to be secured to the inner post, and is to run to the beam afore the mizen step. Fore and aft carling under after lower deck beams.

(483.) The orlop beams for ships of the line to have a fore and aft strake of four inches thick placed under them in the midships, to receive the heads of the pillars in the hold. Strake under orlop beams.

(484.) The half beams are all to be of fir, except those in the cable tiers. Half beams.

Scantlings.

	Ships of the Line, 3 Decks.	Ships of the Line, 2 Decks.	50-gun Ships.	Frigates.
Orlop	Sq. 11	Sq. 10½	Sq. 10	Sq. 8
Lower deck	11	10½	10	8
Middle deck....	10			
Upper deck	9	9	8½	9½
Quarter deck and forecastle ...	7	7	7	7
Roundhouse ...	5½	5½	5	

A piece of oak plank is to be brought on the end of each half beam to make it of sufficient depth to reach the shelf piece.

The midship end of each half beam is to be secured to the carling with a dog-bolt.

Carlings under the midship ends of the diagonal flat for ships of the line. Diagonal ledges. Shelf pieces.

	Br. In.		Dep. In.
(485.) For the gun deck	12	..	10
For middle and upper decks	11	..	9
To be of old oak, thick stuff, or plank.			
For the gun deck about	10	..	5
For middle and upper decks	9	..	4

	Ships of the Line.		50-gun Ships.		Frigates.	
	Inches thick.	Inches broad	Inches thick.	Inches broad.	Inches thick.	Inches broad.
For the orlop .	9	15	8	14	11	11
	To be in	a direc	tion as	shown	by a dra	wing.
Lower deck ..	9	15	8	14	7	12
Middle deck ..	8	14				
Upper deck ..	8	14	7½	13	8	14
Quarter deck and forecastle....	7	12	6½	11	6½	11
Roundhouse ..	6	10	5½	10		

The breadth given is for the upper side of the shelf piece, the front side being bevelled.

(486.) The scarfs to be five feet six inches long, and to be coaked with four circular coaks in each scarf; the scarfs to be so disposed that the front lip may overrun a chock under the shelf piece about four inches.

(487.) Should any difficulty occur in procuring shelf pieces on account of breadth, they may be wrought by bringing the top ends together alternately, and introducing a connecting shift as described in fig. 5.

(488.) The shelf pieces are to be secured with bolts from eighteen to twenty inches asunder, and as the throat bolts of the iron knees will pass through the shelf pieces, no bolt should be placed nearer than twelve inches to the midde of each chock that is intended to receive an iron knee.

(489.) The diameter of the in and out, and up and down bolts for shelf pieces must be as follows:

	Ships of the Line.	50-gun Ships.	Frigates.
Orlop..................	1¼	1¼	1
Lower deck	1¼	1⅛	1
Middle deck............	1⅛		
Upper deck	1⅛	1⅛	1⅛
Quarter deck and forecastle.	1	1	⅞
Roundhouse	⅞	⅞	

Coaks for shelf pieces.

(490.) The diameter of the coaks for the shelf pieces, and the number in each beam end, are to be as follows:

		Ships of the Line.		50-gun Ships.		Frigates.	
		In.	No.	In.	No.	In.	No.
Each beam end and shelf piece.	Orlop..................	4	2	3½	2	4½	1
	Lower deck.............	4½	2	4	2	4½	1
	Middle deck	4	2				
	Upper deck	4	2	3½	2	4	2
	Forecastle and quarter deck	4½	1	4	1	4	1
	Roundhouse	4	1	3½	1		
[Each h]alf beam [an]d shelf [pi]ece.	Orlop	4½	1	4	1	3	1
	Lower deck............	4½	1	4	1		
	Middle deck	4	1				
	Upper deck	4	1	3½	1	3½	1
	Forecastle and quarter deck	4	1	3½	1	3	1

(491.) These coaks are to be of cast iron 4 inches long, and the cavity to be filled with cement and sand; if iron coaks cannot be procured, hard seasoned durable wood coaks are to be substituted.

Chocks for iron knees.

(492.) The chocks under the shelf pieces or beams for iron knees, are to be sided as follows:

	Ships of the Line.	50-gun Ships.	Frigates.
	Inches.	Inches.	Inches.
For the Lower deck	10	9	7
Middle deck.......	9		
Upper deck.......	8½	8	8
Quarter deck and forecastle	7½	7	7
Roundhouse	6	5½	

(493.) The chocks under the orlop shelf pieces are to be placed conformably to directions that will be given with a section, sided for ships of the line and 50-gun ships from eleven to twelve inches, and for frigates from ten to eleven inches. Care is to be taken that the bolts for the diagonal timber in the wake of these chocks, be so disposed as to pass through the chocks.

(494.) The beams of the gun deck, and also those of the orlop, to be stationed so as to receive a side plate, by keeping one side of the chock fair, or in such a direction with the fore or after part of the beam as may be most convenient.

(495.) Side plates for ships of the line five inches broad, 1⅝ inch thick; for 50-gun ships, 4½ inches broad, and 1¼ inch thick, diameter of the bolts 1¼ inch.

(496.) The chocks under the midship lower deck beams of frigates, are to abut on the beam ends of the midship platform in the same manner as those of ships of the line, and 50-gun ships do on the orlop beams, but no side plates are required for frigates.

(497.) The chocks under the shelf pieces are to be got into place as tight as possible, which may be accomplished by previously setting the beams an inch above their proper round.

Forked knees.

(498.) The weights of the forked knees are to be as follows:

	Ships of the Line.	50-gun Ships.	Frigates.
For the Lower deck......	about 3½ cwt.	3	
Middle deck	2¾		
Upper deck......	2¼	2¼	2¼
Quarter deck and Forecastle ...	1½		

(499.) Those beams that are placed over ports where the forked knee cannot with convenience be introduced, are to be secured by iron dagger knees on chocks, with an ear against the side for the introduction of a bolt.

(500.) The diameters of the bolts for the forked knees are to be as follows, *viz.*

Naval Architecture.

		Inches.
Lower deck.	The two throat bolts and the up and down bolt	$1\frac{3}{8}$
	The lower bolts and those fore and aft in beams.	$1\frac{1}{4}$
Upper and middle decks.	The throat, and up and down bolts.	$1\frac{1}{4}$
	Bolts below, and the fore and aft ditto	$1\frac{1}{8}$
Quarter deck and fore-castle.	The two throat bolts, and the up and down ditto.	$1\frac{1}{8}$
	Bolts below, and fore and aft ditto	1

The up and down bolts in the lower, upper, and quarter decks, are to be of copper.

Iron knees under beams.

(501.) The lower deck beams of frigates, and the forecastle and quarter deck beams of 50-gun ships and frigates, to be secured at each end with an iron knee under the beam, in weight $1\frac{1}{2}$ hundred weight, the toes or ends to be $\frac{1}{2}$ inch in thickness and bolted with bolts of one inch diameter.

Round house beams to be secured with plate bolts.

(502.) The beams of the round house are to be secured with a plate bolt at each end, diameter of the bolt in the beam $1\frac{1}{4}$ inch, and bolted with bolts of $\frac{7}{8}$ inch diameter. The plate on which the bolt is clenched is to lie upon the beam and be let into the under side of the flat of the deck.

Beam ends to be secured with bolts driven through the bottom.

(503.) The beams of the orlop and platforms, and the foremost and aftermost beams of the lower decks of frigates, are to be secured with three bolts of $1\frac{1}{8}$ inch in each end, which are to be driven through the bottom of the ship.

Trussing between the ports of ships of the line, 50-gun ships, and frigates.

(504.) The short stuff, or quick work between the ports of the lower, middle, and upper decks, to be composed of materials, sound, well seasoned, and converted from old timber if it can be procured. The abutment pieces for the gun deck to be about thirteen inches broad, and for the middle and upper decks twelve inches.

(505.) The trusses for the gun deck to be eleven inches, and for the middle and upper decks ten inches broad. The abutment pieces are to be the same thickness as the clamps, if they do not exceed six inches, which are not to be bearded, but should they exceed that thickness, they are to be bearded to six inches; but the diagonal trusses are to be half an inch less in thickness.

(506.) Every abutment piece is to be coaked to the port timber, with one circular coak of $3\frac{1}{2}$ inches diameter, which is to be placed so as to act against the pressure of the truss on the abutment piece. The head of each abutment piece is to be bolted with two in and out bolts of $\frac{7}{8}$ inch diameter, each end being also bolted in a fore and aft direction, with one bolt of the like diameter. The space between the trusses and abutment pieces is to be left open, while the ship is in a state of ordinary, but when commissioned it is to be coppered over.

(507.) In calking the trusses between the ports, the horizontal parts in contact with the spirketing and clamp are to be well raimed and calked, by which means they will act well against the up and down, or abutment pieces; but should there be a space left between the abutment pieces and trusses more than the calking will set home, the up and down joint is to be first calked, or a neat iron plate is to be driven in.

Trussing the stern.

(508.) Whether the stern be built in the common principle, or round with the rother head without board, drawings will be sent. The lower, middle, and upper decks of ships of the line, are to be laid diagonally.

(509.) The water ways for the lower deck to be from thirteen to fourteen inches square, and for the middle and upper decks from $12\frac{1}{2}$ to thirteen inches square. These scantlings may be easily procured, as the rabbet and rounding of the front will materially assist the conversion. The rabbet for the flat of the deck is to be taken out, so as to admit of a calking seam of three inches in depth, and with such an angle that the butts of the flat of the deck may be bearded $\frac{3}{8}$ inch and *no more.*

Naval Architecture.

Water ways for diagonal decks.

(510.) To prevent a lodgement of water on the upper side of the water ways, they are to be trimmed below a level from the spirketing, inwards, which may be done by letting the water ways down more on the inner edge, than on that next the timbers, according to fig. 6.

(511.) It being of the greatest importance that the water ways and ekeings be procured of dry, well seasoned oak, or timber of equal durability, great care is to be taken in the selection; and to promote this object, the water ways may be wrought of short lengths and butted on carlings let down for that purpose between the beams, observing that no more carlings are to be introduced than may be necessary for this purpose, and that they be let down in scores which are to be taken entirely from the half beams.

(512.) The carlings are to be of the same breadth as the water ways, and in depth the same as the binding strake, the upper sides of the carlings being flush with the upper sides of the beams. The clamps and spirketing are to be worked according to the usual practice.

(513.) The butts of the water ways are to be disposed of in the middle of the carlings, and the scoring down part of the water way to be taken away from the butt to the side of the beam next to it, as shown in fig. 7, and the binding strakes are to give shift to the water ways.

(514.) Each butt of the water ways is to be secured to the carling with two coaks, and one up and down bolt. The bolt is to pass through the shelf piece, but should the bolt that passes through the end of the half beam come near to the butt of the water way, then one up and down bolt may be omitted. The in and out bolts in the wake of these carlings will necessarily pass through them instead of the water ways.

(515.) No ekeings are to be wrought of greater scantlings than may be necessary to get the water ways in and out of place, and to admit of disposing the up and down bolts so as to clear the rabbet of the water way, the spirketing, and the clamps sufficient for clenching. The ekeings are to give shift to the water ways, and thereby reduce the calking at the butts as well as give a stop to the same.

(516.) The water ways and ekeings are to be scored down on the gun deck main or principal beams three inches, and on the middle and upper deck main or principal beams $2\frac{1}{2}$ inches; the scores are to be taken from the water ways and ekeings, and the butts faced on the sides of the beams $\frac{1}{2}$ an inch. No scores are to be taken from the water ways and ekeings in wake of the half beams, but the scores are to be taken from the half beams entirely.

(517.) One up and down bolt in the water ways through the shelf piece is to be disposed of in the end of each beam and half beam, the diameter of the bolts for the beams of the gun deck to be $1\frac{1}{4}$ inch, and for the middle and upper decks $1\frac{1}{8}$ inch, for the half beams of the gun deck $1\frac{1}{8}$ inch, and for the middle and upper decks one inch.

(518.) The in and out bolts in the upper part of the water ways are to be equal in number to those in the lower part in the binding strakes; the diameter of the bolts for the gun deck to be $1\frac{1}{8}$ inch, and for the middle and upper decks, one inch.

(519.) The diameter of the coaks for the water ways and the number in each beam end to be as follows, *viz.*

Coaks for water ways.

		Inches.	No.
Each beam end water way.	Lower deck	4	2
	Middle and Upper decks..	$3\frac{1}{2}$	2

These coaks are to be of cast iron four inches in length; if iron coaks cannot be provided, then well-seasoned, hard, durable wood is to be substituted.

Side binding or scoring down strakes for securing the ends of the flat of diagonal decks for ships of the line.

(520.) Thick strakes for the gun deck six inches, and for the middle and upper decks five inches, broad ten inches, to be let down in scores taken from the *main* or principal beams; for the gun deck three inches, and for the middle and upper decks $2\frac{1}{2}$ inches; and what may be required to make the upper side of the binding strake flush with the upper sides of the beams, is to be taken from the binding strake, and the scores are to be faced on the sides of the beams half an inch. No scores are to be taken from the binding strakes for half beams, but the scores are to be taken from the half beams entirely.

(521.) One in and out bolt in the binding strake and lower edge of the water way, is to be disposed of in the space between each beam and half beam; and as there will be a space of three inches between the binding strake and water way, no chocks are to be fitted for the purpose of wooding the bolts. The diameter of the bolts for the gun deck to be $1\frac{1}{8}$ inch, and for the middle and upper decks one inch.

Midship binding strakes for the gun, middle, and upper decks of ships of the line, 50-gun ships, and frigates.

(522.) The binding strakes in midships are to be coaked to every main beam and breast hook, with one circular coak of $3\frac{1}{2}$ inches diameter. To be five inches thick from the aft part of the fore hatchway forward for the gun decks of ships of the line, and four inches thick from the ward room or cabin bulk heads forward for middle and upper decks.

Diagonal decks for the gun, middle, and upper decks of ships of the line.

(523.) Every side butt of the flat is to be fastened to the side binding or scored down strake, with two treenails of $1\frac{1}{2}$ inch diameter, except in those beams where the up and down bolts in the forked knees, or the bolts directed for the half beams pass through the flat, then one treenail only is to be driven; the holes for which are not to be bored until the deck shall have been calked, but not payed. All these treenails are to pass through the binding strake, but only one treenail is to pass through each half beam; those in the gun deck main beams being ten inches long, and in the middle and upper deck main beams nine inches long.

(524.) Every midship butt is to be fastened to the main beams, or carlings, as the case may be, with two bolts, and every plank to be bolted with two bolts in each beam, which it may cross; the bolts are all to be $\frac{5}{8}$ of an inch diameter, and eleven inches long, for the gun deck, and eight inches long for the middle and upper decks; the holes are to be bored through the beams, to admit of driving out the bolts. To be fastened to the half beams with two, and to the ledges with one deck treenail.

(525.) One up and down bolt is to pass through the flat of the deck, the side binding or scored down strake, and each main and half beam, excepting those beams of the upper and middle decks, where a knee bolt passes through the binding strake: at the gun deck these bolts will pass through the shelf piece; diameter of the bolts for the gun deck one inch, and for the middle and upper decks $\frac{7}{8}$ of an inch.

Calking diagonal decks.

(526.) The calking of diagonal decks to be carried on progressively, as follows:

1. The treenails.
2. The fore and aft seam, next the binding strake in midships.
3. The diagonal seams.
4. The water way seam.

Care is to be taken that the diagonal seams under the water ways be well filled with oakum, for which purpose irons are to be used similar to those described for that purpose in fig. 8.

Inner or coaked water ways for fore and aft decks.

(527.) The forecastle, quarter deck, and round house of ships of the line, and all the decks of other ships and vessels, to be laid in a fore and aft direction. The coaked water ways for lower decks of 50-gun ships, to be $12\frac{1}{2}$ inches square, and for frigates $10\frac{1}{2}$ inches; for the upper decks of 50-gun ships and frigates, $11\frac{1}{2}$ inches square; for the forecastle and quarter deck of ships of the line, 50-gun ships and frigates, $10\frac{1}{2}$ inches, and for the round house of all ships, to be nine inches square.

(528.) The rabbet to be taken out of the coaked water way, so as to admit of a calking seam of three inches in depth, and with such an angle, that the thin water way may be bearded $\frac{3}{8}$ of an inch, and no more.

(529.) The coaked water ways to be bolted with one up and down bolt in each beam and half beam; the diameter of the bolts for the main beams of the lower decks of 50-gun ships to be $1\frac{1}{4}$ inch, for the upper decks of 50-gun ships and frigates $1\frac{1}{8}$ inch; for the lower decks of frigates, and the forecastle and quarter deck of ships of the line, 50-gun ships, and frigates, one inch, and for the round house of all ships $\frac{7}{8}$ of an inch.

(530.) The diameter of the up and down bolts in the water ways and half beams, to be $\frac{1}{8}$ of an inch less than has been directed for the main beams.

(531.) The in and out bolts for the water ways, to be disposed of at the distance of from twenty inches to two feet asunder, and to be in diameter as directed for the up and down bolts of the respective main beams. This kind of water ways to be butted on carlings, as already described for the diagonal decks.

Coaks for water ways for fore and aft decks.

(532.) Each main beam end and water way to be coaked with circular coaks of cast iron of the following diameters and number.

	Ships of the Line.		50-gun Ships.		Frigates.	
	In.	No.	In.	No.	In.	No.
Lower deck	..		4	2	$3\frac{1}{2}$	1
Upper deck	..		$3\frac{1}{2}$	2	$3\frac{1}{2}$	2
Forecastle and quarter deck	4	1	4	1	4	1
Round house..........	$3\frac{1}{2}$	1	$3\frac{1}{2}$	1		

Outer or thin water way for fore and aft decks.

(533.) The outer water ways to be one inch thicker than the flat of the respective decks, and to be fastened to the beams and half beams with treenails, and the butts to be secured with mixed metal nails.

Forecastle, waist, and quarter deck.

(534.) The forecastle, waist, and quarter deck of ships of the line, 50-gun ships, and frigates, are to be fastened with mixed metal nails.

Bolts for the flat of decks

(535.) The holes for the bolts of diagonal decks are to be bored through the beams to admit of driving out

Naval Architecture.

the bolts on a repair; the bolts are to be made with tool heads, and the points to be rounded for the purpose of driving them out with concave punches.

(536.) In the event of shifting the decks, the holes are to be bored through the new deck, by introducing the auger into the original holes in the beams from the under sides; and to prevent the necessity of re-fastening the bolts of a larger diameter than were originally driven, a rope-yarn or yarns is to be introduced in each hole of sufficient length above the deck to take a turn round the head of the bolt before it may be driven home. But should this mode be found objectionable in practice, either the original mode may be followed by driving bolts of a larger diameter, or the old holes may be plugged up and new ones bored.

Cross bolting of the wood ends forward and aft when transoms are omitted.

(537.) A system of cross bolting is to be introduced between the bolts of the knee of the head and hooks from the orlop upwards, two bolts of $1\frac{3}{8}$ inch diameter for ships of the line, and two bolts of $1\frac{1}{4}$ inch for 50-gun ships and frigates, to be disposed of in each space between the hooks agreeably to fig. 9. No sap wood (except on elm) is to be suffered to remain in any part of the ship, but it is to be taken off from the materials before they are placed in the ship. The officers are to be considered particularly responsible for the performance of this duty.

Sap wood to be taken away.

Circular coaks and holes for ditto painted.

(538.) The holes for circular coaks are invariably to be painted with white lead. Wooden coaks are to be made of the soundest and best seasoned durable wood that can be procured, they are to be soaked in oil, and their ends painted with white lead. In all cases great care is to be taken that the holes are not sunk lower than the coaks themselves, and where double sunk coaks are used great care is to be taken to fill up the space with chalk and grease as before directed.

Oil and tar.

(539.) In all cases where oil and tar have been directed to be used, the mixture is invariably to be made with four-fifths of oil and one-fifth of tar.

Copper bolts for iron knees.

(540.) Every copper bolt for iron knees, is to be driven with a ring under its head, and those copper bolts which are clenched upon the bottom under the line of flotation, are to be carefully chinced, and putty placed upon the oakum before the ring is put on.

Beams to be placed erect for seasoning.

(541.) In order to facilitate the seasoning of beams they are to be converted as early as possible, and placed as near the ship as convenient, with their butt-ends upwards; and as oil has been found to be a great preventive to the dry rot, the butt-ends of these important parts of the ship are to be hollowed out so as to retain a quantity of oil, by which means it will be most readily absorbed by the timber; a fresh supply of oil is to be afforded occasionally, and, in trimming the beams, as little of their ends so saturated, is to be cut off as possible. The ends of the beams are to be covered, so as to protect them from water, and admit a free circulation of air.

Means to be taken for the preservation of the materials.

(542.) Defects are to be cut out of timbers of the frame, and all other parts of the ship, before they are stowed away for seasoning; and those timbers where defects have been removed, the hole is to be on the under side, but if that cannot be done, a hole is to be bored to take off the water.

(543.) The faying part of the various materials, *viz.* diagonal timbers, fore and aft pieces, trusses, hooks, crutches, chocks under beams, the water ways and ekeings to ditto are to be charred with shavings or ironed with a hot iron, and while hot to be payed with oil and tar.

(544.) All the timbers of the frame in the hold of the ship, but particularly those under the magazine and coal-hole, *when perfectly dry*, are also to be payed over with oil and tar twice or more during the time the ship is building. The rents and shakes of the frames, and also the diagonal framing, are to be chinced, and the surface well payed with oil and tar.

(545.) The ends of beams, longitudinal pieces, trusses, chocks, under-shelf pieces, carlings, &c. after being well saturated with oil and tar, are to be painted with white lead. By this process the capillary tubes will be prevented from absorbing the juices of the timber with which they are to be brought in contact.

Openings, &c. to be kept clear of chips, &c.

(546.) The strictest attention is to be paid during the building of the ship, to keep the openings of the frame and every other part clear from chips or dirt, or any thing that may obstruct a free circulation of air.

Entrances to hold.

(547.) An entrance to the hold is to be left open in all ships at the head, and also on one side in midships as long as the carrying on of the works will admit, not only for the convenience of conveying the materials on board, but to facilitate the seasoning of the ship by creating a circulation of air; which latter object will be further promoted by leaving open the treenail holes in various parts until the calking of the ship. The calking of the ship is not to be performed until it shall be considered necessary. A strake is to be left open on the outside, opposite to the opening above the strake on the orlop beams within board.

(548.) When a ship is not built or repaired under a roof, every possible precaution is to be taken to keep her dry during the progress of the works; and to accomplish this desirable object, the forecastle, quarter deck, and round house are to be laid and calked as early as possible, and a temporary housing erected over the waist. Eave boards are also to be fitted to the topside, as already practised, to carry the water from the ship. If necessity should compel the use of unseasoned timbers, it is to be boiled in the kilns, and afterwards exposed to the air as long as possible.

(549.) Fig. 1, 2, and 3, pl. vi. represent the sheer plan or elevation, the body plan or plan of projection, and the half-breadth plan of a first-rate of 120 guns.

Commercial marine of Great Britain.

(550.) Great Britain is not only deeply interested in all that concerns her Navy, but also in that commercial marine, which connects her with other nations. When we look at the magnitude of this portion of her power, at once the ample feeder of her wealth, and a nursery of seamen for all the daring enterprises of war, we cannot but regard every improvement by which additional security can be imparted to it, with the greatest interest and delight. By the modes of ship-building commonly practised in our merchants' yards, Sir Robert Seppings observes there can be little doubt that lives and property to an immense amount must from time to time be sacrificed by injudicious modes of construction, and by the inefficient plans which have had no better origin than a rude and barbarous experience.

Its importance.

(551.) An idea of the great importance of our commercial marine may be gathered from the following statement of the British shipping employed in the trade of the United Kingdom, and which have actually entered the several Ports of Great Britain for some preceding years.

Commercial shipping for 1831

	1826	1827	1828	1829	1830
British Tonnage	1,796,250	1 972,790	1,955,548	2,033,854	2,036,091

(552.) For the year 1831 we present a more detailed

list of the shipping employed in the trade of the United Kingdom, together with the number and tonnage of vessels entered inwards and cleared outwards, (including their repeated voyages,) with the number of their crews; separating British from Foreign ships, and distinguishing the trade with each Country.*

Imperfect mode by which merchant ships are at present constructed

(553.) With regard to the principle on which mercantile ships are at present constructed, and particularly as regards the putting together their ribs or frames, and the arrangement of the materials, it may be observed, that in forming the frames or ribs, half of the timbers only are united so as to constitute any part of an arch, the alternate couples only being connected together; the intermediate timbers (termed fillings) being unconnected together, and merely resting upon the outer planking, instead of giving, as they ought to do, support to it. Ships so constructed cannot by any means possess equal strength with those that have the whole of their timbers formed into frames or arches.

(554.) Sir Robert Seppings observes, "that this imperfect mode of practice is peculiar to the English merchant ship-builder; and was pursued even till very lately in his Majesty's Navy, while the preferable system of connecting the ribs was common to other maritime Powers. There cannot be any doubt," he further adds, "that the principle of uniting the frames now adopted in the construction of English ships of war, might with great advantage be also introduced into the mercantile Navy; thereby giving to the ships in that employ additional strength and increased durability, without adding to the expense of building.

Principles employed in Navy might with advantage be adopted in merchant ships.

(555.) There are also great objections to the present

mode of joining together the several pieces of the same rib. In the ordinary way it is done by the introduction of a third piece, technically termed a chock or wedge piece, A, fig. 4. pl. vi.; these pieces amounting to upwards of four hundred and fifty in a 74-gun ship, and not less than that number in an Indiaman of 1200 tons. Of these chocks, not one in a hundred is ever replaced in the general repair of a ship, being not only found defective, but very generally to have communicated their own decay to the timbers to which they are attached. In addition to this, the grain of the rib pieces is much impaired, to give them the curvature required; and that they occasion a great consumption of materials, is obvious, the ends of the two rib pieces being first cut away, and then replaced by the chock.

Great objections to the present mode.

This mode peculiar to the English ship-builder

(556.) This mode of putting together the frame is also peculiar to the English ship-builder, and was introduced about the year 1714; and to the honour of Mr. Nash, the builder of the Royal William, it should be recorded, that he refused to adopt it. When that ship was taken to pieces at Portsmouth, in 1813, Sir Robert Seppings found she was built without the wedge pieces or chocks, to which, in a certain degree, he attributed her strength and durability.

Why chocks were introduced.

(557.) Chocks were no doubt introduced in order to procure the necessary curvature, when crooked or compass timber became scarce, as may be seen in fig. 5. The same curvature, however, may equally be obtained by a different combination of materials, and at a considerable less consumption of useful timber.

Description of frames of a mercantile ship.

(558.) The frames of a mercantile ship, according to the present mode of building, before they are placed and united to each other, may be seen with their chocks or wedge pieces in fig. 6. From imperfect workmanship, also, the surfaces of the chocks are seldom in contact with those of the timbers; and the ends of both are frequently reduced so thin, as to split by the fastenings necessary to secure the planks to the ribs. Thus the ship, in the event of grounding, or even in the act of rolling, derives little support from timbers united only by two narrow edges.

Defects.

(559.) Another great defect, moreover, is, that the ends of the lower ribs or timbers, commonly termed the lower futtocks, fig. 6, are not continued across the keel C, so that no support is given in a transverse direction when the ship touches the ground; nor any aid to counteract the constant pressure of the mast. This great sacrifice of *strength* and *safety* is made for no other purpose than that of giving a passage for the water to the pumps.

(560.) The floor timbers, which by this mode of construction are the only timbers that cross the keel, are also weakened for the same purpose, as shown at D, fig. 6. The conveyance of the water is hence very uncertain, the passage being very frequently choked; the pumps, from its not being practicable to continue them sufficiently low, always leaving from six to eight inches of water in the ship. These compartments, therefore, constantly permit a certain quantity of putrid bilge water, offensive and injurious to the health of all on board.

(561.) The deficiency of strength causes also an alarming insecurity in the plank of the bottom, as shown at E, fig. 6, termed the garboard strake; which, consequently, has no other fastening to the general fabric than its connection with the keel at F, fig. 6, and a slight security at G, fig. 6: hence it is obvious, that in the event of the keel being disturbed, the garboard strake, from its being attached to it, must share the same fate as the keel, and in that case the loss of the vessel would be inevitable.

Improvements of Seppings.

(562.) To obviate these serious defects is the principal object of the excellent Paper given by Sir Robert Seppings in the *Transactions of the Royal Society for* 1820. The principle of this improvement may be seen by referring to fig. 7, the component parts of each rib being of shorter lengths and less curvature, and consequently less grain-cut. They are also rendered more firm and solid by substituting coaks or dowels for chocks or wedge pieces; and the mode of connecting the lower timbers is better adapted, in the event of a ship grounding, to give support and strength to the fabric, as appears by the line denoted by H.

Origin of the idea of dowels or coaks.

(563.) This mode of connecting the ends of the timbers by circular dowels or coaks, as at I, is that which has, from time immemorial, been practised to unite the fellies of carriage wheels; and we learn from Mr. Wood, that the same method has been observed in joining together the separate pieces of the shafts of the stone columns in the ruins of Balbec.

Comparison of the Talavera and Black Prince.

(564.) To contrast the two systems, the Talavera, built according to the new plan, was compared with the Black Prince, constructed with chocks, the result being most favourable to the former. The frame of the Talavera was composed of small timber, hitherto considered applicable only for the frames of frigates. Sir Robert was induced to attempt the construction in this way; from there being a surplus store of small timber in the yard, and from a conviction, that a well-combined number of small timbers might be made equal, if not superior, both in strength and economy, to the large, overgrown, and frequently grain-cut materials, employed in constructing the frames of large ships. The result has shown the correctness of the principle; and its adoption cannot fail to prove of great national advantage, in the application of sloop timber to the building of frigates, and of frigate timber to ships of the line, whenever large timber cannot be procured. On this principle, also, may frigates and small ships of war, or merchant vessels, be built of straight fir, without the assistance of oak or elm, formerly employed to give the necessary curvature of the sides.

Timber commonly applied to small ships may be used for larger ships.

Further description of the principle.

As respects the general safety of the ship, it may be seen, by referring to fig. 8, pl. vi., and fig. 10, pl. v., that the timbers uniformly cross the keel; that the frame of the ship is filled so as to form a compact body to the height marked K; and that only certain internal strakes of plank, or thick stuff, as it is termed, are introduced on the joints of the timbers, for the purpose of imparting strength where every alternate timber necessarily joins, as shown at L. The remainder of the inner planking may be omitted, and dunnage battens, in a perpendicular direction, brought upon the timbers *between* the plank, as shown at M, thereby forming regular spaces between each, as is usual at present *upon* the plank. This will give an increase of stowage in proportion to the thickness of the plank omitted. Water courses, denoted by dotted lines at N, are left in the joints of the timber under the plank, for the purpose of conveying the water to the pumps; which, by this plan, reach below the water, instead of being some inches above, as in former plans. No stagnant water will hence remain, the limber passage, forming a smooth uniform channel, capable of being cleared with ease, should it be required, whenever the hold is unstowed; whereas at present it is inaccessible

in places, and forms compartments for putrid water, without there being any means of removing it.

A ship so constructed may lose planks from its bottom, and also lose its keel.

(565.) It is obvious that a ship constructed on this principle may sustain the loss of certain planks of the bottom, and, also the keel, (which has frequently happened to ships of war on their being taken into dock,) and still reach the place of her destination; when the loss of *either* would be the destruction of a ship built on the present mode. It is evident, also, that a ship constructed on the new plan possesses greater capabilities of stowage, and ampler space for leakage than by the old; by omitting the useless inner planking, and by laying the kentlage on dunnage, leaving a space for the water, which was formerly occupied by the inner lining. This dunnage in the bilge may be formed with the iron kentlage, and thereby serve as ballast, for which it is well calculated from its situation; and by its occupying a space heretofore forming part of the fabric of the ship, cannot but give an increase of stowage.

Mode of closing the openings between the timbers.

(566.) The best mode of closing the openings between the timbers, is by filling the intermediate spaces with pieces of wood, about three inches in depth, and of such lengths as the inferior conversions will afford. These fillings are to be well calked, after which the exterior plank is to be brought on. When the works are going on within board, similar pieces are to be fitted internally, and afterwards taken out for the purpose of filling the spaces between the pieces so fitted with a mixture of Parker's Roman cement and drift sand, in the proportion of two to one, the opening being previously well payed with coal tar. Where there is sufficient space, a brick may be introduced, provided there is room for cement between it and the timbers. When filled in to within about two inches of the surface of the frame, the three-inch pieces, already fitted and taken out, are to be well driven in and calked, thereby leaving no space unoccupied. These pieces may even be driven below the surface of the timber, leaving water courses to convey the leakage to the pumps in channels. Before the launching or undocking of ships built on this principle, it has been the practice to inject the part filled in with mineral tar, by means of a simple forcing pump, boring holes in the joints of the timbers for the introduction of the pipe. By following this method, the air will be excluded, which, as experience has shown, tends much to the durability of the fabric. If what is here recommended be attended to, and mercantile ships be built under roofs, as ships of war now are, durability will be obtained in addition to safety, from the mode of their construction.

How wooden knees are rendered unnecessary.

(567.) The beams are to be attached to the sides, as shown at O, fig. 8. rendering wood knees unnecessary, and requiring only a small number composed of iron. In fig. 11, pl. v. the portion P illustrates the old principle of framing the stern with transoms, and Q the new one, having timbers similar to the bow, omitting the transoms below the wing or upper transom. By introducing the new principle on which the floors are made, the necessity of using the valuable compass timber, hitherto required, and which is with so much difficulty procured, is altogether avoided. Uniform support is thus given, and also increased room for stowage. In mercantile ships above 500 tons, Sir Robert Seppings recommends plate iron to be laid diagonally, as shown in fig. 10, pl. v.

Plate iron to be laid diagonally.

Proof of strength of the Malabar.

(568.) The important principle now recommended, not only causes a decrease in the consumption of materials, and obviates the difficulty of procuring the necessary curvature, but also affords protection from worms externally, and vermin internally. Leaks may be more easily discovered and stopped than by the old method; and as a beautiful experimental proof of increased strength the Malabar, of 74 guns, built at Bombay, arrived at Portsmouth, loaded to her upper deck with timber, having during her passage encountered four heavy gales of wind, without showing a symptom of weakness. This ship had no other attachment for her beams than the internal hoops and thick water way; the iron knees having been omitted, from the difficulty of procuring them in India, until her arrival in this Country; thus supporting her cargo without the aid of knees, either of wood or iron.

Mr. Edye's valuable Tables.

(569.) The publication of Mr. Edye's valuable Work on *Naval Calculations*, has brought the great numerical results of ship-building into a very convenient point of view. The praiseworthy industry that has led to the formation of the numerous Tables contained in it, will, we hope, meet with its due reward. To the theoretical cultivator of Naval Architecture, as well as to the practical shipwright, this collection of constants cannot but prove of the greatest value.

Dimensions of different ships.

The following Table contains the dimensions* of different ships, with their light and load draughts of water and height of ports.

* We regret that our limits will not permit us to do more than allude with the greatest brevity to the important history of the dimensions of ships. It has been by very slow and gradual steps that our Navy has advanced in this important particular. In 1677 the length on the gun deck of a 100-gun ship, amounted but to 165 feet, and in the establishment of 1745 it had increased only to 178 feet. Spain was the first nation that increased the dimensions of ships to any considerable extent, and France followed her example with better success. The capture of the Princess of 70 guns from the Spaniards in 1739, pointed out the necessity of our increasing the dimensions of our largest class of two decks; but the French and Spanish Navies were long inferior to the English in the want of three-deckers, of which experience taught them the largest classes were much too powerful for their largest two-deckers. It was not till after the Peace of 1763, that either France or Spain possessed a single ship of three decks. It was the English three-decker, the Royal George of 100 guns, and of 2046 tons burthen, launched in 1756, that gave so great an impulse to ships of this class. The Commerce de Marseilles, however, exceeded our present first-rates in length by 3 feet 4 four inches, in breadth by 1 foot 3 inches and a half, and in tonnage by 145 tons.

By adopting 100 for the breadth of a three-deck ship of each of the following Nations, the proportional lengths are those recorded in the following Table:

	Proportional Breadth.	Numbers for the Length.
Spanish	100	358
Swedish	100	372
French	100	380
English	100	383

And in the largest class of ships of two decks of 80-guns and upwards, these proportional numbers are as follows:

Spanish.............	100 Breadth.	362 Length
Danish	100	367
Swedish.............	100	369
French	100	375
English.............	100	376

By taking the smaller ships of two decks, the proportional numbers become:

English	100 Breadth.	361 Length.
Spanish	100	365
Swedish.............	100	365
French	100	365
Danish	100	373

And for frigates, we have the following:

Spanish.............	100 Breadth.	367 Length.
French (Impérieuse) ..	100	375
English (Leda)	100	376
Danish	100	377
Swedish	100	379
French (Niobe)	100	383
English (Portland) ...	100	398

Analysis of the rates of labour.

(570.) An exact analysis of the rates of labour of the different artisans employed in building a ship of war, cannot but be of the greatest value.

In the following Table we have the rates per ton, and also the total amounts.

The Rate per Ton for Labour on all Classes of Ships and Vessels with the Total Amount.

Great difference in rates of labour for different ships.

(571.) It appears from this Table that the rates of labour for the different classes of ships are by no means constant. In the shipwrights, for example, there is a difference between the maximum rate for the 28-gun ship, and the minimum rate for the 52-gun frigate, amounting to no less than £1. 15*s*. 2*d*, per ton. It would be curious to trace the cause of so great a difference. The cheapest ship for the calkers and joiners is also the 52-gun frigate; but the maximum price for the former trade is found in the 10-gun brig and the schooner; and for the latter trade, the greatest price is found in the 120-gun ship, and the 18-gun corvette. The greatest rate of labour for the smiths is found in the 46-gun frigate, and the least in the cutter. The cheapest vessel for the painters is the 18-gun brig, and the dearest the three-decker. Taking all the ships, the dearest vessel per ton is the 28-gun ship, and the cheapest the 52-gun frigate. We might pursue these comparisons further, did our limits permit.

* From these sums 20 per cent. must be deducted to bring them to the Peace rates.

Other relations of rates of labour and materials.

(572.) The relations, also, of the rate per ton for labour and materials are deserving, also, of an attentive consideration. In the fourth and fifth columns of the succeeding Table, this relation is exhibited, the timber exceeding the labour in the greatest ratio in the 120-gun ship, and the least in the 18-gun brig.

Loads of timber for different ships.

(573.) The next Table contains a statement of the loads of rough timber, plank, &c. required for building each class of ship and vessel; of the quantity that one man can work up in a twelvemonth in building; and of the number of men it will take to complete a ship in that time for launching, calculated at the War rate.

Number of men to build a ship of each class.

Rate of Ship	120	80	74	52	46	28	Corvette. 18	Brig. 18	Brig. 10	Schooner.	Cutter.
Quantity of Loads required	5880	4339	3600	2372	1800	963	624	471	337	250	186
Ditto, that one Man can work in a Twelvemonth	29½	28¾	29¾	25¾	23¾	22	18½	17½	18½	18½	17
Number of Men to build a Ship in the same period	200	153	122	91½	76	44½	33¾	27¾	18	13½	11
If estimated at the Peace rate, the following will be the results.											
Quantity of Loads for one Man in a Twelvemonth.............	35½	34¼	35¾	30	28½	26	22¼	21	22	22	20½
Number of Men to build a Ship in the same period	160	122½	97	69	60¾	35½	27	22¼	14½	10¾	8¾

Number of men to rig a ship of each class.

(574.) The time in which 20 riggers can fit the rigging and blocks of each class of ship and vessel is given in the following Table:

Class of Ship and Vessel.	Hours.
120 Guns	300
74 to 60	285
50	260
46	230
28	140
18 Corvette	110
18 Brig	105
10	80

(575.) With this Table we reluctantly quit the important subject of Naval Architecture. It is one of growing interest to the World, and the present distinguished Surveyor of the Navy, Captain Symonds, in the ships already built and now building by him, has so largely increased the dimensions of ships, that we cannot but anticipate the most splendid results from his important plans.

* 20 per cent. must be deducted from these sums for labour, and 18 per cent. for materials, to reduce them to the Peace rates. The Cornwallis of 74 guns, of 1809 tons, was built at Bombay of teak, at £30. 14*s.* a ton. The Trincomalee frigate, of 1065 tons, at the same place, of the same material, at £29. 8*s.* 2*d.* per ton. The Victory, also, of 382 tons, at £23. 9*s.* 7*d.* a ton; the Zebra, of 385 tons, at £21. 6*s.* 7*d.* a ton; the Sphinx, of 239 tons, at £24. 6*s.* 6*d.* a ton; and the Camden, of 240 tons, at £25. 3*s.* 10*d.* a ton.

THE following Treatise has, for the accommodation of different classes of readers, been divided into two Parts.

In the First an explanation is given of the relations of Crystals, founded upon the characters and positions of their planes; and in the Second, those relations are investigated and demonstrated mathematically.

The following characters are used in this Treatise.

A, E, I, O, on the angles of primary terminal planes. (98.)

B, C, D, F, on the primary terminal edges. (98.)

G, H, on the primary lateral edges. (98.)

P, M, T, on the primary planes shown in the figures. (98.)

$\|$ P, $\|$ M, $\|$ T, primary planes parallel to P, M, T. (106.)

v, general expression of the law of decrement. (124.)

$\overset{v}{A}$, $\overset{v}{E}$, &c., simple decrement on the terminal angles. (124.)

A_{v}, E_{v}, &c., *general* symbol of simple decrements on the lateral angles. (124.)

$\overset{r}{B}$, $\overset{r}{H}$, &c., decrements on terminal or lateral edges. (125.)

(B_r, B'_y, B''_r) intermediary decrement. (127.)

0, no decrement, absence of any symmetrical plane, (127.) as $\overset{r}{\underset{0}{B}}$, when only the upper plane of mod. *e* of the cube occurs in the Crystal, (127.) or $\overset{0}{A}$ $\overset{v}{A}$, when a plane occurs only on the alternate angles. (128.)

(0) absence of a symmetrical intermediary plane. (127.)

a, *b*, *c*, &c., on the modifying planes.

$\bar{a}$, $\bar{b}$, $\bar{c}$, $\bar{d}$, modifying planes on the angles of the doubly oblique prism, and $\bar{e}$, of the oblique rhombic prism, when they cut the *terminal* plane parallel to a diagonal. (106.)

$,a$, plane *a* of doubly oblique prism when it cuts M parallel to a diagonal. (106.)

$a_,$, the same modification when it cuts T parallel to a diagonal, (106.) and so of $,b$, $b_,$, $,c$, $c_,$, &c.

$b_{,,}$, &c., when an angle is modified by *two* symmetrical planes, as in the square prism, which cut the lateral planes parallel to a diagonal. (103.)

$\frac{b}{2}$, when only one of such planes appears on the left in the Crystal. (103.)

$\frac{b}{2}$, when the single plane is on the right. (103.)

$\frac{b}{2}$ *r*, when only one of two *intermediary* planes occurs on the right. (103.)

$l\frac{b}{2}$, when the single plane occurs on the left. (103.)

$\frac{a}{2}$, $\frac{b}{2}$, &c., when planes occur only on the *alternate* angles or edges of the cube. (100.)

$\frac{a}{2}\|$, $\frac{b}{2}\|$, &c., when the angles or edges of the cube are modified by only one half the number of planes required by the law of symmetry. (101.)

m, *n*, *o*, comparative lengths of primary edges. (133.)

p, *q*, *r*, comparative lengths of edges of the defect. (121.)

P,*a*, P,*b*, *a*,*b*, &c., inclination of P on *a*, or *b*, of *a* on *b*, &c. (81.)

PART I.

Definitions and Explanations.

(1.) The object of the Science of Crystallography, regarded as a branch of Mineralogy, is to describe and explain the relations which subsist among the various crystalline forms of minerals, so as to enable the Mineralogist to determine the species of a mineral from the characters of its Crystals.

These relations will be explained by first separating the Crystals into groups, and then selecting one from each group as a standard, with which the remainder of the group may be compared.

(2.) The standard so selected will be termed the *primary form*, and the remainder of the group *secondary forms*, as will be afterwards more fully explained.

(3.) A *Crystal*, in Mineralogy, is any mineral solid, whether transparent or opaque, contained within *natural* surfaces, generally plane, but occasionally curved, and symmetrically arranged.

(4.) These surfaces, as *a*, *b*, *c*, fig. 1, are called *planes* or *faces*, and to distinguish them from such as are developed by splitting a Crystal, they are called its *natural planes*.

The plane *a*, and that on which the figure is supposed to rest, are by some authors called *summits*, or *bases*, but they are more conveniently distinguished as *terminal planes*; the planes *b* and *c*, and those parallel to them, are *lateral planes*.

(5.) Crystals may sometimes be split in directions parallel to their natural planes, and frequently in other directions.

The splitting a Crystal in any direction, so as to produce a new plane, is termed *cleaving* it, and the Crystal is said to have a *cleavage* in the direction in which it may be so split.

(6.) The planes produced by cleaving a Crystal are called its *cleavage planes*. But when a cleavage merely separates adjacent Crystals, without dividing the Crystals themselves, the planes then developed are termed *planes of composition*.

Both the natural and cleavage planes of Crystals are sometimes found to differ in lustre and other characters according to their position on the Crystal.

(7.) An *edge*, as *d*, fig. 1, is the line produced by the meeting of two planes.

If the two planes which produce an edge, are those of a primary form, the *edge* is termed *primary*. If they are secondary, and belonging to the *same modification*, the *edge* is termed *secondary*. But if an edge be produced by the meeting of a primary and a secondary plane, or

of different secondary planes, it is termed *an edge of combination.*

The edges of the terminal planes, as *d*, *e*, *m*, *n*, fig. 1, are *terminal edges*, and *f*, *g*, *h*, produced by the meeting of the lateral planes, are *lateral edges*.

(8.) A *plane angle*, or, as it is more commonly termed, *an angle*, is formed by the meeting of any two lines or edges, which are sometimes said to *contain* the angle. The angles *d o e*, *d o g*, fig. 1, are formed by the meeting of the lines *d o*, *o e*, and *d o*, *o g*.

(9.) A *solid angle* is produced by the meeting of three or more planes, as at *o*, fig. 1.

(10.) The *measure*, or, as it is sometimes termed, the *value of an angle*, is the number of degrees, minutes, &c. of which it consists; these being determined by the portion of a circle which would be intercepted by the two lines forming the angle, supposing the point of their meeting to be in the centre of the circle.

For the purpose of measuring angles the circle is divided into 360 equal parts, called *degrees*; each degree into 60 *minutes*; each minute into 60 *seconds*; each second is sometimes further subdivided into 60 *thirds*; and so on if more minute divisions be required. And these divisions are thus respectively designated, 360°, $60'$, $60''$, $60'''$.

If one fourth of the circle be intercepted by the two lines *a o*, *o b*, fig. 2, which meet at an angle *a o b* in the centre, those lines are perpendicular to each other, the angle they contain is 90°, and is termed a *right angle*.

If less than one fourth of the circle be so intercepted, as by the lines *o b*, *o c*, the angle *b o c* is less than 90°, and is said to be *acute*. If it measure more than 90°, as it would if the angle were formed by the lines *a o*, *o c*, it is called *obtuse*.

(11.) The *planes* of a Crystal are said to be *similar* when their corresponding edges are proportional and their corresponding angles equal.

(12.) *Edges* are *similar* when they are produced by the meeting of planes respectively similar at equal angles.

(13.) *Angles* are *similar* when they are equal, and contained within similar edges respectively.

(14.) *Solid angles* are *similar* when they are composed of equal numbers of plane angles, of which the corresponding ones are similar.

(15.) The homogeneous particles, by the regular aggregation of which Crystals are conceived to be produced, are termed *molecules*; and these are assumed to be separable, but not divisible, by splitting or otherwise breaking the Crystal.

These *molecules*, which relate properly to the Crystal, must, when the crystallized mineral is not a simple body, be carefully distinguished from the *elementary particles* of which the mineral itself is composed. Sulphur and lead are the elementary particles of galena, in which they are chemically united; but it is the *molecules* of galena which are conceived to form the crystalline mass.

(16.) The same species of mineral is frequently found crystallized in a considerable variety of forms.

(17.) The term *form* as it is used here, and as it will be employed throughout this Treatise, does not refer to the actual figure of any particular Crystal, but to that perfect figure which the Crystal would present if all its parts were truly proportional and symmetrical.

Thus one of the *forms* of the Crystals of fluate of lime is a cube, all of whose planes are equal squares; but the *actual figures* of the Crystals which represent that form, are probably never contained under equal square planes, but under unequal rectangular ones, which differ also in different Crystals.

(18.) From among the various forms belonging to any species of mineral, some particular one may be selected from which the others might be derived in a manner which will be afterwards explained. This form does not, however, always occur among the *natural* Crystals of a species, but is sometimes inferred from cleavage or other circumstances.

This parent Crystal has been already termed a *primary form*, and the others which are conceived to be derived from it, *secondary forms*.

(19.) The selection of a figure which is to be regarded as the primary form of a species, is in some degree arbitrary, as will be afterwards shown. And the number of different primary forms is also within certain limits a matter of choice.

The following have been adopted in this Treatise, because they appear to afford the most simple explanations of the relations of Crystals, and thus tend to facilitate the study of this important and interesting branch of Mineralogy.

(20.) The *cube*, fig. 3, contained within six square planes. The *regular tetrahedron*, the *regular octahedron*, the *rhombic dodecahedron*, and the *pentagonal dodecahedron*, and their modifications, are secondary forms of the cube, and will consequently be referred to that figure as their primary form.

(21.) A *right prism* with a *square base*, or *square prism*, fig. 4, in which the edge B is always greater or less than G. The *octahedron with a square base*, and its modifications, will be referred to this prism as its primary form.

(22.) A *right rhombic prism*, fig. 5, whose lateral planes M, M′ are equal. These planes may be either square or rectangular. The *octahedron with a rhombic base*, and the *right rectangular prism*, with their modifications, are secondary forms of this prism.

(23.) An *oblique rhombic prism*, fig. 6, whose lateral planes M M′ are equal, oblique-angled parallelograms. The *right oblique-angled prism* and its modifications will be referred to this form.

(24.) A *doubly oblique prism*, fig. 7, whose terminal and lateral planes are oblique-angled parallelograms. The only equality subsisting among these planes, is between each pair of parallel ones.

(25.) The *rhomboid*, fig. 8, a solid contained within six equal rhombic planes, and having two of its solid angles, *a*, *b*, composed of three equal and similar plane angles; these are sometimes called *summits*.

The *regular hexagonal prism* being a secondary form of the rhomboid, will be referred to that figure as its primary form.

(26.) The *secondary* forms of Crystals consist of all those varieties which differ from the primary, and which, although extremely numerous, may be arranged in a few general groups, as will appear in the sequel.

(27.) The *general group*, or *series* of Crystals, related to either of the preceding primary forms, constitutes what is sometimes termed a *system of Crystallization*.

(28.) And a *particular group*, or *individual series* of Crystals, belonging to a *particular mineral*, to whatever *system* it may appertain, is sometimes termed a *series of Crystallization*.

(29.) A line, as *i k*, or *p q*, fig. 1, drawn through

two opposite angles of any parallelogram, and dividing it into two equal parts, is called a *diagonal* of that plane.

In the oblique rhombic prism, fig. 6, the doubly oblique prism, fig. 7, and the rhomboid, fig. 8. The line *a c*, which appears to lean from the spectator, is termed the *oblique diagonal*, and the line *f g* of the oblique rhombic prism, and *d f* of the rhomboid, the *horizontal diagonal*.

The line *d f* of the doubly oblique prism may also, for the sake of uniformity, be termed its horizontal diagonal; although from the nature of the figure, that line must be in some degree oblique when the lateral edges are perpendicular.

(30.) The *diagonal plane* of a solid, as *i k p q*, fig. 1, is an imaginary plane passing through the diagonal lines of two parallel planes, dividing the solid into two equal parts.

A diagonal plane passing through the oblique diagonal of the oblique rhombic prism or rhomboid is termed the *principal section* of each solid.

(31.) The *axis* of a Crystal is an imaginary line passing through the centre of the solid.

That which also passes through the centres of the terminal planes of a cube or prism is termed a *prismatic axis*.

From the regularity of figure of the cube it may be said to have a prismatic axis in three directions.

That which passes through two opposite solid angles of a cube or prism is termed an *oblique axis*.

That which passes through the centres of two lateral planes of a prism may be termed a *horizontal axis*.

The axis of a pyramid passes through its terminal point and through the centre of its base.

The axis of a rhomboid is a line passing through its two summits.

The diagonals and axes of Crystals and the diagonal planes are frequently referred to in describing the forms of Crystals.

(32.) A Crystal is said to be *in position*, when it is so placed, or held, as to permit its being the most easily and precisely observed and described.

The cube rests on one of its planes, and all prisms on their respective bases.

The rhomboid is supposed to be held with its axis vertical.

(33.) The different primary forms stand in the following relations to each other.

If we imagine the lateral edges of the cube, fig. 3, to be lengthened or shortened, a square prism would be produced.

It will facilitate our description of the relation of some of the primary forms to certain others, if we conceive the edges to be formed of wires, united at the solid angles by universal hinges or joints, and thus rendered movable in every direction; and, together with the axis, capable of being lengthened or shortened.

If we conceive one of the oblique axes of the cube to be lengthened, the resulting figure would be an *acute* rhomboid. If the axis were shortened by bringing two opposite solid angles nearer together, an *obtuse* rhomboid would be produced.

If two opposite lateral edges of a square prism be supposed to approach each other, so as to shorten one of the diagonals of the terminal plane and lengthen the other, the resulting figure would be a right rhombic prism; and if this prism were forced from its perpendicular in the direction of either of the diagonals of its terminal plane, an oblique rhombic prism would be produced.

And if this were again made oblique in the direction of a terminal edge, a *doubly oblique prism* would be the result.

(34.) The first formation of a Crystal is supposed theoretically to take place by the aggregation of a few homogeneous molecules around a single central one, so as to produce a small solid precisely similar in form to the molecules composing it.

(35.) Crystals so formed are conceived to increase in magnitude by the continual additions of laminæ, or plates of similar molecules to their surfaces.

These plates are theoretically supposed to be either single, that is, of the thickness of single molecules, or to be double, triple, &c., that is, of the thickness of two, three, or more molecules.

Fig 9. represents a single plate of molecules.

Fig. 10 represents a double plate.

(36.) When the added plates successively envelope the whole of a smaller Crystal, its original form is preserved through every increase of size, as is shown in fig. 11, representing a square prism which has increased in magnitude without change of form. When the additions do not cover the whole surface of a primary plane, but there are rows of molecules omitted on the edges, or angles of the superimposed plates, such omission is called *a decrement*; because the primary form on which the diminished plates are successively laid, appears to decrease, as it were, on the edge or angle on which such omissions take place.

(37.) *Decrements* are said to begin at, or to set out from, the particular edge or angle at which the omission of molecules first takes place; and to proceed along that plane on which the defective plates of molecules are laid; and they are said to take place either in breadth or in height.

Decrements in breadth are those which result from the reduction of the superficial area of the superimposed plate, by the abstraction of rows of molecules from its edges or angles.

Decrements in height relate to the thickness of the plate from which the abstraction of rows of molecules takes place.

Decrements are divided into two principal classes, *simple* and *intermediary*.

(38.) *Simple decrements* are those in which one or more rows, in breadth, are abstracted from plates of one or more molecules in thickness.

Fig. 12 exhibits a simple decrement by one row in breadth on the edge *c d* of the primary form.

Fig. 13 exhibits a simple decrement by one row in breadth on the angle *c* of the primary form.

For the sake of rendering the expression *rows of molecules* generally applicable to decrements both on the angles and edges of a primary form, the term *row* is applied to express the *single molecule* first abstracted from the *angle* of any plate.

In fig. 14 the single molecule *a b* is regarded as the *first row* to be abstracted from the angle of the imaginary plate; the two molecules *c, d* as the *second row*; the three molecules *e, f* as the *third row*, and so on.

Fig. 15 shows a simple decrement by two rows in height on the edge *c d* of the primary form.

Fig. 16 shows a simple decrement by two rows in height on an angle of the primary form.

It is observable in these figures, that each successive plate is less by one row of molecules than the plate on which it rests. It is by this continual recession of the edges of the added plates, that the Crystal appears to decrease on its edges or angles, and that new planes are produced. The edges of the new planes which would be produced by the four preceding decrements, are shown by the lines *a b c d*, fig. 12 and 15, and by the lines *a b c*, fig. 13 and 16.

When the numbers of molecules in height and breadth are different, the nature of the decrement is expressed by a fraction, of which the *numerator*, or *upper figure*, denotes the *number of molecules in breadth*, and the *denominator*, or *lower figure*, the *number in height*; thus a decrement denoted by $\frac{1}{2}$ would imply an abstraction of a single row from a plate of two molecules in thickness, and one denoted by $\frac{4}{3}$ an abstraction of four molecules in breadth and three in height.

(39.) *Intermediary decrements* affect only the solid angles of Crystals, and may be conceived to consist in the abstraction of rows of small masses of molecules from the successively superimposed plates, each mass, or as it may be termed, *compound molecule*, containing unequal numbers of single molecules in length, breadth, and height. Thus if we suppose the compound molecule abstracted in an intermediary decrement to belong to a single plate, it must consist of some other numbers of molecules in the directions *d* and *e*, fig. 17 and 18.

In fig. 17 the compound molecule consists of a single molecule in height, two on the edge *d*, and three on the edge *e*, producing the new plane *a b c*.

Fig. 18 exhibits an intermediary decrement in which the compound molecule consists of three single molecules in height, four on the edge *d*, and two on the edge *e*, producing the new plane *a b c*.

It may be remarked, that the planes produced by simple decrements intersect one or more of the primary planes in lines parallel to one of their edges or diagonals. The term intermediary has been used, because the line at which the secondary plane thus produced intersects a primary plane, is never parallel to either an edge or diagonal of that plane, but is an intermediate line between them, as may be observed by comparing the figures.

(40.) The new planes produced by decrements are denominated *modifying* or *secondary planes*, and the primary form, when altered in shape by the interference of such planes, is said to be *modified* on the edges or angles on which they have been produced. And such edges or angles are also said to be *replaced* by the secondary planes.

(41.) The *law* of a decrement, or, as it is sometimes expressed, of a plane, is a term used to denote the numbers of molecules in height and breadth abstracted from *each* of the superimposed plates, in the production of such plane.

(42.) It is evident from an inspection of the preceding figures that the effect of any decrement upon the primary form is similar to that which would take place if the enlarged Crystal had been first completed, and then the whole of the omitted molecules removed from it in one mass.

This mass, being all the addition to the secondary form which would be required to complete the primary, will be termed *the defect* of the primary form. And it is obvious from the preceding figures that the primary edges of this *defect* must be composed of edges of molecules respectively proportional to the numbers which express the law of decrement.

Thus in fig. 13 each edge of the defect would consist of the edges of three molecules, and these being respectively divided by 3 correspond to a decrement by one row.

The edge of the defect of fig. 15 corresponding to the lateral edge of the prism must consist of four molecules, and the edge corresponding to the terminal edge of the prism of two molecules; which numbers agree with the law of decrement, the proportion of 4 to 2 being the same as that of 2 to 1.

This theory of decrements, as it will be afterwards seen, is introduced for the purpose of rendering the explanations of the manner in which the secondary forms of Crystals may be conceived to be produced more distinct.

(43.) When an edge, or solid angle, is replaced by one plane, it is said to be *truncated*. When an edge is replaced by two planes, which respectively incline on the adjacent primary planes at equal angles, it is *bevelled*.

(44.) If any secondary plane replacing an edge, and being parallel to it, incline equally on the two adjacent primary planes, or if replacing a solid angle, it incline equally on all the adjacent primary planes, it is called a *tangent plane*.

Of the Goniometer.

(45.) The instruments used for measuring the angles at which the planes of Crystals incline to each other, are called Goniometers.

(46.) The mutual inclination of any two planes, as of *a* and *b*, fig. 19, is indicated by the angle formed by two lines *e d*, *e f*, drawn upon them from any point *e* on the edge at which they meet, and perpendicular to that edge.

Now it is known that if two right lines, as *g f*, *d h*, fig. 20, cross each other at any point *e*, the opposite angles *d e f*, *g e h* are equal.

If, therefore, the lines *g f*, *d h* are supposed to be very thin and narrow plates, and to be attached together by a pin at *e*, serving as an axis to permit the point *f* to be brought nearer either to *d*, or to *h*; and that the edges *e d*, *e f*, of those plates, are applied to the planes of the Crystal, fig. 19, so as to rest upon the lines *e d*, *e f*, it is obvious that the angle *g e h* of the movable plates would be exactly equal to the angle *d e f* of the Crystal.

(47.) The *common* Goniometer is a small instrument for measuring this angle *g e h* of the movable plates. It consists of a semicircle, fig. 22, divided into 360 equal parts, or half degrees, and a pair of movable arms *d h*, *g f*, fig. 21. The semicircle having a pin at *i*, which fits into a hole in the movable arms at *e*.

The method of using this instrument is, to apply the edges *d e*, *e f* of the movable arms to the two adjacent planes of any Crystal, so that they shall accurately touch or rest upon those planes *in directions perpendicular to their edge*. The arm *d h* is then to be laid on the plate *m n* of the semicircle, fig. 22, the hole at *e* being suffered to drop on the pin at *i*, and the edge nearest to *h* of the arm *g e* will then indicate on the semicircle, as in fig. 23, the number of degrees which the measured angle contains.

When this instrument is applied to the planes of a Crystal, the points *d* and *f*, fig. 21, should be previously

brought sufficiently near together for the edges $d\,e$, $e\,f$, to form a more acute angle than that about to be measured. The edges being then gently pressed upon the Crystal, the points d and f will be gradually separated, until the edges coincide so accurately with the planes that no light can be perceived between them.

The *common* Goniometer is, however, incapable of affording very precise results, owing to the occasional imperfection of the planes of Crystals, their frequent minuteness, and the difficulty of applying the instrument with the requisite degree of precision.

(48.) The more perfect instrument, and one of the highest value to Crystallography, is the *reflective* Goniometer, invented by Dr. Wollaston, which will give the inclination of planes whose area is less than $\frac{1}{10000}$ of an inch, to less than a minute of a degree.

This instrument has been less resorted to than might, from its importance to the Science, have been expected, owing, perhaps, to an opinion of its use being attended with some difficulty. But the observance of a few simple rules will render its application easy.

The principle of the instrument may be thus explained.

Let $a\,b\,c$, fig. 21, represent a Crystal, of which one plane only is visible in the figure, attached to a circle, graduated on its edge, and movable on its axis at o; and let a and b mark the position of the two planes whose mutual inclination is required.

And let the lines $o\,e$, $o\,g$, represent imaginary lines resting on those planes in directions perpendicular to their common edge, and the dots at i and h to be some permanent marks in a line with the centre o.

Let the circle be in such a position that the line $o\,c$ would pass through the dot at h, if extended in that direction, as in fig. 24.

If the circle now be turned round with its attached Crystal, as in fig. 25, until the imaginary line $o\,g$ is brought into the position of the line $o\,c$ in fig. 24, the number 120 will stand opposite the dot at i.

This is the number of degrees at which the planes a and b incline to each other. For if the line $o\,g$ be extended in the direction $o\,i$, as in fig. 25, it is obvious that the lines $o\,e$, $o\,i$, which are perpendicular to the common edge of the planes a and b, would intercept exactly 120° of the circle.

Hence an instrument constructed upon the principle of these diagrams, is capable of giving with accuracy the mutual inclination of any two planes which reflect objects with sufficient distinctness, if the means can be found for placing them successively in the relative positions shown in the two preceding figures.

(49.) This purpose is effected by causing an object, as the line at m, fig. 26, to be reflected successively from the two planes a and b, at the same angle.

It is well known that the images of objects are reflected from bright planes at the same angle as that at which their rays fall on those planes; and that when the image of an object reflected from a horizontal plane is observed, it appears as much below the reflecting surface as the object itself is above it.

If therefore the planes a and b, fig. 26, are successively brought into such positions, as will cause the reflection of the line at m, from each plane, to appear to coincide with another line at n, both planes will be successively placed in the relative positions of the corresponding planes in fig. 24 and 25.

To bring the planes of any Crystal successively into these relative positions, the following directions will be found useful.

(50.) The instrument, as shown in the sketch, fig. 27, should be first placed on a pyramidal stand, and the stand on a small steady table, about six to ten or twelve feet from a flat window.

The graduated circular plate should stand perpendicularly from the window, the pin x being horizontal, not in the direction of the axis as it is usually figured, but with the slit end nearest to the eye.

Place the Crystal which is to be measured on the table, resting on one of the two planes whose inclination is required, and with the edge at which those planes meet, nearest and parallel to the window.

Attach a portion of wax, about the size of d, to one side of a small brass plate e, fig. 28; lay the plate on the table with the edge f parallel to the window, the side to which the wax is attached being uppermost, and press the end of the wax against the Crystal until it adheres; then lift the plate with its attached Crystal, and place it in the slit of the pin x, with that side uppermost which rested on the table.

Bring the eye now so near the Crystal as, without perceiving the Crystal itself, to permit the images of objects reflected from its planes to be distinctly observed, and raise or lower that end of the pin x which has the small circular plate on it, until one of the horizontal upper bars of the window is seen reflected from the upper or first plane of the Crystal, corresponding with plane a, fig. 21, and until the image of the bar appears to touch some line below the window, as the edge of the skirting board where it joins the floor.

Turn the pin x on its own axis also, if necessary, until the reflected image of the bar of the window coincides accurately with the observed line below the window.

Turn now the *small* circular handle a on its axis, until the same bar of the window appears reflected from the second plane of the Crystal corresponding with plane b, fig. 24 and 25, and until it appears to touch the line below; and having, in adjusting the *first* plane, turned the pin x *on its axis* to bring the reflected image of the bar of the window to coincide accurately with the line below, *now move the lower end of the pin laterally*, either towards or from the instrument, in order to make the image of the same bar, reflected from the *second* plane, coincide with the same line below.

Having ascertained by repeatedly looking at and adjusting both planes, that the image of the horizontal bar, reflected successively from each, coincides with the observed lower line, the Crystal may be considered ready for measurement.

Let the 180° on the graduated circle be now brought opposite the 0 of the vernier at c, by turning the handle b; and while the circle is retained accurately in this position, bring the reflected image of the bar from the *first* plane to coincide with the line below, by turning the *small* circular handle a. Now turn the graduated circle, by means of the handle b, until the image of the bar reflected from the *second* plane is also observed to coincide with the same line below. In this state of the instrument the vernier at c will indicate the degrees and minutes at which the two planes incline to each other.

The accuracy of the measurements taken with this instrument will depend upon the precision with which the image of the bar reflected successively from both planes is made to appear to coincide with the same line

below: and also upon the 0, or the 180°, on the graduated circle, being made to stand precisely even with the lower line of the vernier when the first plane of the Crystal is adjusted for measurement.

A wire being placed horizontally between two upper bars of the window, and a black line of the same thickness being drawn parallel to it below the window, will contribute to the exactness of the measurement, by being used instead of the bar of the window and any other line.

Persons beginning to use this instrument, are recommended to apply it first to the measurement of fragments at least as large as that represented in fig. 28, and of some substance whose planes are bright. Crystals of carbonate of lime will supply good fragments for this purpose, if they are merely broken by a slight blow of a small hammer.

For accurate measurement, however, the fragments ought not, when the planes are bright, to exceed the size of that shown in fig. 27. And they ought to be so placed on the instrument, that a line passing through its axis should also pass through the centre of the minute fragment which is to be measured. This position on the instrument ought also to be attended to when the fragments or Crystals are large. In which case the common edge of the two planes whose inclination is required, should be brought very nearly to coincide with the axis of the Goniometer; and it is frequently useful to blacken the whole of the planes to be measured, except a narrow stripe on each close to the edge over which the measurement is to be taken.

Of the Origin and Progress of Crystallography, and of the different Systems which have been formed for explaining the Relations of Primary and Secondary Forms.

(51.) It does not appear that this Science was even known to the Ancients, or that the few crystalline forms with which they were acquainted were otherwise regarded by them than as mere accidental figures.

Linnæus was the first who bestowed any particular attention upon this subject.

Among the numerous observed forms of Crystals, there are some which belong only to particular minerals, and others which are common to different species. Thus the cube occurs as a form of fluate of lime and of galena. The regular octahedron as that of alum, the diamond, and the ruby.

Observing that the form of the octahedron was common to the diamond and to alum, Linnæus conceived that the salts were in some manner the generators of the forms of Crystals, and that a mineral which agreed with a salt in its form, might in regard to form be considered a subspecies of that salt. Hence the diamond was denominated alum diamond, and a remote analogy was imagined to exist between his systems of Crystallography and Botany.

This author appears to be the first who published figures of Crystals, and he is regarded by Haüy, from whom we have extracted many of these preliminary observations, as the founder of the Science of Crystallography.

This title is, however, more justly due to Romé de l'Isle, who made the first extensive collection of Crystals, and was the first to arrange together those belonging to each known species of mineral; and having selected from each group so arranged some simple figure, as the fundamental or derivative form from which the remainder might be produced by *cutting away* its edges and angles, he reduced all the forms belonging to each set into a connected series; and he thus exhibited for the first time an outline of the relations of crystalline forms to each other.

He also published figures of the Crystals he had observed, with the measurements of many of their angles, from which it appeared that the corresponding planes on all the Crystals belonging to the same species of mineral, inclined to each other at the same angle; this, it is evident, was an important step in the progress of the Science of which we are about to treat.

As the subject was new in his hands, the labour of arranging and analyzing all the forms he had observed, and measuring their angles, must have been very considerable. The want, however, of instruments well adapted to measure the angles of Crystals with accuracy, exposed him, as might have been expected, to numerous errors, which have been corrected by later observations.

Werner, to whose persevering industry Mineralogy is so much indebted, also invented a method of describing Crystals by reference to certain fundamental forms.

His method, however, although it might be applied to simple and regular figures, will be found too cumbrous for the description of such as are contained under numerous planes. We may refer such of our readers as desire to know more of this nearly obsolete system to Brochant's *Traité Elémentaire de Minéralogie*, Paris, 1808; or to the second edition of Professor Jameson's *Mineralogy*.

The preceding methods, it may be observed, are merely descriptive, and relate simply to the forms of Crystals, without reference to any theory of structure, or to any laws by which the relations of the observed varieties of form might be explained. No attempt is made to ascertain the cause of the constancy of the angles of inclination of corresponding planes of Crystals belonging to the same mineral, nor do these methods provide any means of determining, *à priori*, the forms under which any species of mineral may present itself, from a knowledge of its simple fundamental Crystal.

(52.) Bergman was the first who attempted to penetrate into the interior structure of Crystals, and to refer their observed variations of form to the superposition or plates of crystalline matter upon the planes of a fundamental solid; these plates being sometimes constant in figure, and sometimes variable.

This theory was supported by the fractures of one of the Crystals of carbonate of lime, known in this Country by the name of dog-tooth spar, contained within twelve scalene triangular planes, and forming a bi-pyramidal figure. One of these Crystals may be easily split so as to exhibit only the six planes of a rhomboid, which was in theory conceived by Bergman to represent the nucleus, or basis, upon which the twelve-sided figure had been constructed. But Bergman did not pursue the inquiry upon which he had thus successfully entered. He neither determined the nature of his crystalline plates, nor the forms of the particles of which they might be conceived to be composed, nor the laws connected with their variable character.

Nearly at the time, however, that Bergman was engaged in these researches, Crystallography occupied the zealous attention of Haüy, whose investigations embraced the forms and dimensions of the molecules of which these plates might be composed, and who was

thus led to a strict demonstration of the laws which might govern their arrangement; and thus for the first time Crystallography assumed the character of a regular Science.

His theory is founded upon a supposition that all the crystalline forms which are presented by any single species of mineral, and which are known sometimes to be numerous, are related to some simple form, which may be regarded as a general type of all the known Crystals belonging to the species.

This simple form is conceived to be composed of particles either similar in figure to itself, or bearing some known and constant relation to that figure. It is also supposed to be contained, as an *inscribed solid*, within all the Crystals which differ from it in external figure, and the observed differences of external figure are supposed to depend upon the laws according to which the added particles arrange themselves about the contained solid.

To render this theory consistent with the observed facts, it is obvious that the form which is adopted as the type of the species should not be chosen arbitrarily, and that the assumed laws of arrangement of the enveloping particles should be capable of precise and rigorous demonstration.

The method adopted by Haüy to develope this type or fundamental form, was by splitting or cleaving the Crystal, and he was induced from the following considerations to conclude, that this fundamental form might always be so derived.

A Crystal of carbonate of lime presenting the form of a regular hexagonal prism, had been broken from a group of similar prisms. On examining it he observed that the fractured surface exposed by its detachment from the group was a bright plane, and on more narrowly inspecting this fracture he observed that a terminal edge of the prism had been removed by it.

On perceiving this, he attempted to remove all the terminal edges by analogous fractures, but he found that only the alternate three of the six edges which terminate a prism of that form, could be so displaced.

The fig. 29 exhibits the directions of the three cleavage planes at each extremity of the prism; the three below being severally parallel to the three above.

By continuing to cleave this Crystal parallel to all the newly developed planes, the faces of the hexagonal prism were observed successively to disappear, and when they were at length entirely removed, a new solid remained which was an obtuse rhomboid.

The fig. 30 exhibits the rhomboid in the interior of the hexagonal prism.

The idea which this fact suggested to Haüy's mind was, that all the Crystals of carbonate of lime, whatever might be their external form, might possibly contain similar rhomboids; yet it was difficult at first to conceive how this particular solid should be the nucleus of more acute and more obtuse rhomboids which occur among the Crystals of this substance.

Experiment, however, proved, that this particular rhomboid did exist in a symmetrical position in each of those forms which differed from it externally; the only point to be attended to in developing the nucleus being the direction of the necessary cleavage. This may generally be perceived by looking through the Crystal when exposed to a strong light; or it may be ascertained by slightly fracturing a terminal edge or angle. Haüy states, that all other mineral substances, when submitted to mechanical division, have afforded analogous proofs of the generality of this result; a statement however not strictly correct, as there are several minerals which do not admit of being cleaved into regular solids, and others from which two or more different solids may be obtained by cleavage.

The forms of the solids thus obtained by mechanical division he terms *primitive*, upon the supposition of their corresponding in figure with the original minute solid upon which the Crystal was first formed.

But the production in many instances of several solids from the same Crystal by cleavage, and the impossibility in others of producing any solid by that process; the inconsistency of admitting several primitive forms of the same mineral, and the impossibility of producing any such primitive form when there are not cleavages in at least three directions; have induced us to abandon altogether the notion of a *primitive* solid, and to distinguish this original or parent figure by the term *primary form*, denoting simply its relative character to the secondary forms derived from it.

From the mechanical division to which many Crystals may be subjected, Haüy was led to the conclusion that every Crystal was from its centre to its surface an assemblage of molecules symmetrically disposed; and although his views of its structure regarded a certain portion of its mass as an imaginary nucleus, or elementary solid, upon which subsequent increments had taken place, the existence of this nucleus is assumed only as a theoretic basis for calculating and demonstrating the laws according to which all the varieties of crystalline forms related to it might be produced.

Haüy's theory next supposes that nature has set limits to the angles at which the primary planes of Crystals incline to each other; a supposition which does not appear to be supported by a single fact. The circumstance which led him to this conjecture was an inaccurate measurement of the Crystal of carbonate of lime, which afforded the first clue to his theory of the structure of Crystals; an inaccuracy occasioned by the unfitness of the instrument he employed to measure Crystals with exactness.

We have not in this Treatise followed Haüy in classing and naming Crystals, but have adopted and generalized a method of description first introduced by Bournon.

By a reference to any of his descriptions of minerals in the *Transactions of the Geological Society*, or to Bournon's *Treatise on Carbonate of Lime*, it will be seen that he has arranged and numbered all those individual modifications of the primary form of the mineral described, which had been found to occur among its secondary forms. Our proceeding has been to reduce into classes in the tables of modifications not only all the *observed* modifications of Crystals, but *all the modifications of which each particular primary form is susceptible while influenced by the laws of symmetry.* Thus presenting to the reader not merely the series of known forms, but the entire system of possible forms which can result from regular Crystallization; and hence every new form which may be discovered, if it be conformable to those laws, will be found among those presented by our tables.

(53.) Within a few years two new systems of Crystallography have been produced in Germany. One by Professor Weiss, and the other by Professor Mohs, now of Vienna.

Crystallography.

These systems differ from each other in notation and in some other points, but they agree in using the axes of Crystals to express the relations of the secondary to the primary forms.

The following statement exhibits the relations of the four systems of primitive forms of Professor Mohs to our classes of primary forms.

Mohs's systems	*consists of the*	
1. The rhombohedral......	rhomboid.	
2. The pyramidal.........	square prism.	
3. The prismatic	right rhombic / oblique rhombic / doubly oblique	prisms.
4. The tessular	cube.	

The reader who may be desirous of seeing more of this very uninviting system, both in notation and nomenclature, will find it developed in a Work on Mineralogy published in this Country by Mr. Haidinger, an able and intelligent pupil of Mohs.

Of the Molecules of Crystals.

(54.) The Molecules which are aggregated together in the production of Crystals, are, as already stated, conceived to be minute homogeneous solids contained within symmetrically-disposed plane surfaces. And they are also supposed to differ in figure in the different classes of primary forms.

(55.) If we attempt to fracture a piece of galena, it will split into rectangular fragments. But as the primary Crystal of galena is a cube, it is assumed, that if the rectangular fragments could be reduced to single Molecules, those Molecules would be cubes.

(56.) If a Crystal of carbonate of lime be reduced to fragments, it is found that their planes, however minute, incline to each other at angles respectively equal to those of the primary rhomboid. It is therefore inferred that the Molecule of carbonate of lime is a minute rhomboid, similar to the primary form.

(57.) The primary form of sulphate of barytes has been ascertained from cleavage, and from its secondary planes, to be a right rhombic prism. This prism may be split into smaller right rhombic prisms, whose angles are respectively equal to those of the primary Crystal. It is therefore supposed that the primary Crystal and the Molecules of this substance are similar prisms.

Some other classes of parallelopipeds may also be split into fragments, resembling in their angular measurement the primary solids from which they have been detached, and it is hence inferred generally that the primary forms and their respective Molecules are similar solids.

(58.) In several instances, however, cleavage does not produce this primary solid.

A cube of fluate of lime, for example, does not yield that figure by cleavage, but, as will be shown in the section on cleavage, it will split into regular octahedrons, or tetrahedrons, or rhomboids whose plane angles are 60° and 120°.

Haüy has assumed the octahedron as the *primitive* form of this mineral, and has regarded the tetrahedron as the Molecule of the octahedral Crystal, upon which supposition the octahedron must be composed of tetrahedral solids united by their points, leaving octahedral spaces; and he has also supposed that the tetrahedron, when that is the predominating, and in his view, the primitive form, is constituted of tetrahedral Molecules and octahedral spaces.

Of the Molecules of Crystals.

The rhombic dodecahedron may be cleaved into obtuse rhomboids, obtuse octahedrons, and irregular tetrahedrons, as will be shown in the section on cleavage. Of these, Haüy has selected the irregular tetrahedron for the Molecule of the dodecahedron, and has supposed that the decrements on this form are produced by the abstraction, not of single Molecules, but of several of these combined in the figure of those obtuse rhomboids which are produced from it by cleavage.

The very complicated view of the structure of the octahedron and dodecahedron, which Haüy has thus introduced into his theory of Crystals, and the apparent improbability that the Molecules of the cube, the regular octahedron, tetrahedron, and dodecahedron, among whose primary and secondary forms so perfect an indentity subsists, should really differ from each other, have induced us to conclude that they are similar, and that the common Molecule is a cube.

(59.) This theory of cubic Molecules may be reconciled with the cleavages which take place parallel to the primary planes of the tetrahedron, the octahedron, and the rhombic dodecahedron, as well as to those of the cube, by supposing the Molecules capable of being held together with different degrees of attractive force in different directions. When this attraction is least in a direction perpendicular to the planes of the Molecules, they will be most easily separated at their surfaces by cleavage.

When the attraction is least in the direction of the oblique axis of the Molecules, they will be the most easily separated in that direction, and the octahedron or tetrahedron will be the result of cleavage.

And if the attraction be least in the direction of their diagonal planes, a rhombic dodecahedron will be the solid produced by cleavage.

This supposition of a greater or less degree of molecular attraction in one direction of the Molecule than in another, is not inconsistent with many well-known facts in Crystallography; and it is possible to conceive that the nature, the number, and the particular forms of the *elementary* particles, which enter into the composition of these three kinds of cubic Molecules, may so vary, as to produce the variety of character which is here supposed to exist.

The primary form both of corundum and of carbonate of lime is a rhomboid; and the Crystals of these substances may be cleaved parallel to their primary planes, the carbonate of lime yielding much more readily to cleavage than the corundum. But the corundum has also a cleavage perpendicular to its axis, which does not exist in carbonate of lime, and which would expose the terminal solid angles of the contiguous Molecules. It may therefore be inferred from this transverse cleavage that the molecular attraction is comparatively less in the direction of the axis of the Molecules of corundum, than it is in those of carbonate of lime. And from the greater adhesion of the planes of corundum, than of those of carbonate of lime, it is inferred that the attraction is comparatively greater between the planes of the Molecules of the corundum, than between those of carbonate of lime.

While, however, we thus attempt to reason concerning Molecules, it must not be forgotten that the whole theory of decrements and Molecules is to be regarded

only as the foundation of a method of demonstrating the relations of Crystals, and of constructing descriptive characters, by which those relations may be expressed.

It must also be admitted that we possess no certain knowledge relative to the figures of the ultimate particles of matter. They have been supposed by some to be minute spheres or spheroids, but whether they are plane or curvilinear solids, they present anomalies when in particular states of combination which have not been hitherto explained.

The crystalline form of native silver is a cube, and its Molecules are therefore supposed to be cubes.

The *natural* crystalline forms of sulphur may be referred to a right rhombic prism as the primary, and which is therefore assumed to be the form of the Molecules. Yet the form of the compound of sulphur and silver is a cube.

Now whether the Molecules be possessed of plane or curved surfaces, it is difficult to suppose that the cube of silver and the rhombic prism of sulphur should both be composed of Molecules which are similar in form. And if they are not similar, it is equally difficult to account for the compound of silver and sulphur assuming the form of a cube.

We have in the two crystalline forms of iron pyrites (composed of iron and sulphur) an example of a cube and a right rhombic prism being both produced by the same chemical compound; and it is also found that sulphur itself will assume two different forms, according to the circumstances under which the Crystallization takes place. The cause, however, of this dimorphous character of some substances is not at all understood.

Of the Structure of Crystals.

(60.) It has been already stated that Crystals are conceived to increase in magnitude by the continual addition of plates of molecules to their surfaces.

The *Structure* of Crystals, *or the order in which these molecules are arranged*, may be illustrated by an experiment with common salt. If a portion of this salt be dissolved in water, and the water be allowed to evaporate slowly, rectangular Crystals will be deposited on the sides and bottom of the vessel. These will at first be very minute, but they will increase in size as the evaporation proceeds; and if the quantity of salt dissolved be sufficient, they will at length attain a considerable magnitude.

If the edge of a knife be applied to the surface of any one of these Crystals in a direction parallel to one of its edges, as at *a b*, fig. 32, the Crystal may, by a slight blow, be cleaved parallel to one of its sides.

If a knife be applied in the same manner successively to the other lines *c d*, *e f*, *g h*, and to the other surfaces of the Crystal, so that its edge be parallel in each instance to the edge of the Crystal, it will be found that there are cleavages parallel to all the planes of the rectangular solid; and the plates which have been removed by these cleavages may be also subdivided into smaller solids of the same character.

It is hence inferred that the molecules of Crystals are so arranged as to form plates in the direction of all the primary planes, as shown in fig. 11. And that in common salt the molecular attraction is least between the surfaces of the molecules.

This regular Structure is supposed to belong to all regularly crystallized bodies, although in many instances it cannot be manifested by cleavage.

(61.) It frequently happens that the regular Crystallization of bodies has been prevented by some disturbing cause which has interfered with that orderly arrangement of the molecules necessary to the constitution of perfect crystalline structure; in this case the crystalline mass will be curved or otherwise irregular, or from the minuteness of the separate Crystals and their variety of position it may present a granular character. This granular character would be produced if the solution we have supposed of common salt were rapidly evaporated and suddenly cooled.

Of Cleavage.

(62.) The Cleavage of Crystals is sometimes an important mineralogical character.

The direction in which the Cleavage of a Crystal lies may frequently be perceived by turning the Crystal round in a strong light, although it cannot be readily cleaved in that direction.

(63.) When a Crystal may be cleaved parallel to the primary planes, and also in other directions, it is said to have two or more *sets* of Cleavages. Those which are parallel to the planes of the primary form, are called the primary set, and those which are not parallel to those planes, are termed supernumerary sets.

The oxide of tin, described by Mr. Phillips in the *Geological Transactions*, has three sets of cleavages; one parallel to the planes of an obtuse octahedron with a square base, and two others perpendicular to that base and parallel to its edges and diagonals.

Different specimens of the same substance will occasionally yield to the knife or hammer with different degrees of facility; and even carbonate of lime, which in general splits with ease and regularity, will sometimes present a conchoidal fracture.

(64.) Some practice is necessary in order to cleave minerals neatly, and some little experience in the choice of the instruments to be used.

In many instances, the mineral being placed on a small anvil of iron or lead, a blow with a hammer will be sufficient for dividing it in the direction of its cleavage planes; and sometimes a knife or small chisel may be applied in the direction of those planes, and pressed with the hand, or struck with a light hammer, or the Crystal may be held in the hand, and split with a small knife; or it may be split by means of a pair of small cutting pincers with *parallel edges*; and a small short chisel, fixed with its edge outward in a block of wood, is sometimes a convenient instrument for resting the mineral to be cleaved upon.

(65.) When all the planes of a primary form are similar, as those of the cube and rhomboid, the primary Cleavages may be effected with equal facility in all directions, and the cleavage planes are all similar in lustre and general character. This may be illustrated by cleaving galena and carbonate of lime.

But where the planes of a primary form are not all similar, as in all prisms, the primary Cleavages are rarely effected with equal facility in the directions of the dissimilar planes, nor do the cleavage planes agree in their general characters. Hence the cleavage planes of a mineral may occasionally prove that it does not belong to a particular class of primary forms, although the

Cleavage alone is not, in all cases, sufficient to determine what the primary form really is.

Felspar, kyanite, and sulphate of lime, afford instances of the greater facility with which a Cleavage takes place in one or two directions than in any other.

(66.) There are among minerals some substances which yield readily to mechanical division in one or two directions, but do not admit of distinct Cleavage in a third direction, so as to produce an entire solid.

This circumstance has introduced into Mineralogy the terms *single, double, triple, quadruple, and sextuple* Cleavage, which are not to be confounded with the primary and supernumerary *sets* of Cleavages before alluded to.

When a mineral can be split in *only one direction*, the Cleavage is said to be *single;* when in *two* directions, which may be conceived to give four sides of a prism, it has a *double* Cleavage; when there is a Cleavage in *three* directions, such as to produce a solid bounded by six planes, which are parallel when taken two and two, it is termed a *triple* Cleavage.

A *quadruple* Cleavage, or one in *four* directions, will produce a tetrahedron, an octahedron, or an entire hexagonal prism.

The rhombic dodecahedron being contained within *six* pairs of parallel planes lying in different directions, is produced by a *sextuple* Cleavage.

Supernumerary Cleavages either alone, or combined with the primary, may produce solids contained under greater numbers of planes.

In the preceding sections on molecules and structure, some of the results of Cleavage have been noticed. The subject, however, requires to be further illustrated.

(67.) A cube of fluate of lime does not split in directions parallel to its planes as galena does, but splits obliquely. Let fig. 33 represent a cube of this mineral.

If the edge of a knife be applied to the diagonal line *a b* of this cube, and the knife inclined in the direction of *e*, the solid angle *a b e c* may be removed.

If the edge of the knife be again applied to the same line *a b*, and struck in the direction of *f*, another solid angle *a b f d* may be removed, and applying the knife in the direction of the line *c d*, two other solid angles *a* and *b* may be detached.

The new solid produced by these Cleavages is represented by fig. 34.

If the knife be applied successively to the lines *i k*, *k l*, *l m*, *m i*, fig. 34, and struck in the direction of *n*, the remaining solid angles of the cube may be removed, and the regular octahedron *i k l m n o* will be produced.

It is apparent that the solid angles of this octahedron must touch the middle points of the planes of the cube, its position in which is shown by fig. 35.

This octahedron may be further cleaved in a direction parallel to its own planes.

If it be cleaved parallel to six only of its planes, omitting any two parallel ones, and the Cleavage be continued until only the central points of the two parallel ones remain, a figure of six sides will be produced.

This figure is a rhomboid whose plane angles are 60° and 120°.

Fig. 36 shows the position of this rhomboid in the octahedron, from which it is evident that the Cleavage which produces it must be continued as far as the lines *i k*, *l m*, *n o*, and to those which are parallel to them on the opposite plane.

Fig. 37 exhibits the same rhomboid separately, and it may be regarded as an octahedron with two of its planes covered by small tetrahedrons, *p f r s* and *t u x*. These tetrahedrons are supposed to consist of masses of cubic molecules, and by their removal, as in fig. 38, a perfect octahedron will be reproduced.

If an octahedron be cleaved parallel to any four *alternate* planes, fig. 39, the Cleavage be continued until only the central points of the other four planes remain, a regular tetrahedron will be produced, as shown by the interior lines.

The tetrahedron thus obtained, fig. 40, may be regarded as an octahedron, four of whose planes are concealed, or covered by smaller tetrahedrons, *p q r s*, *p q u t*, *u q x v*, *q x r y*, and by the removal of these it may be reduced to a perfect octahedron.

The tetrahedron and octahedron have thus obviously the same set of Cleavages, and the octahedron may be regarded as an imperfect tetrahedron, requiring certain additions to complete that form.

(68.) A cube of blende will split in directions parallel only to its diagonal planes. These Cleavages will truncate the edges of the cube, and if continued until all the edges are removed, and the faces of the cube disappear, a rhombic dodecahedron will be produced.

Fig. 41 shows the position of the rhombic dodecahedron in the cube, in which six of its solid angles touch the middle points of the planes of the cube.

If this dodecahedron, fig. 42, be cleaved parallel to the planes *a, d, i, m*, and to the four planes parallel to these, until the four remaining planes of the dodecahedron disappear, an obtuse octahedron will be produced.

Fig. 43 exhibits this octahedron separately, the planes being marked by the same letters as appear on the corresponding planes of the dodecahedron.

If the Cleavage be effected parallel only to the planes *a, d, e*, and those parallel to them, until the other primary planes disappear, an obtuse rhomboid will result, as seen in fig. 44; this rhomboid measures 120° over the edges at which the planes *a* and *e* meet.

If the Cleavage takes place parallel to any four *alternate* planes of the obtuse octahedron, and be continued until the four cleavage planes alone remain, an irregular tetrahedron, fig. 45, will be produced, whose planes meet at an angle of 90° at the edges, *n o*, *p q*, and at an angle of 60° at the other edges.

The ultimate relation of the tetrahedron to the octahedron in reference to the theory of cubic molecules, may be explained in the following manner.

Let fig. 47 represent the smallest octahedron that can be imagined to exist, formed of seven cubic molecules, and let fig. 46 represent a tetrahedron containing this minute octahedron. The tetrahedron would obviously be reducible to the octahedron, as other tetrahedrons are, by the removal of all its solid angles. But it is apparent that the solid angles to be removed in this instance, are the small cubes *a, e, g, i*, and on their removal the octahedral solid, shown in fig. 47, will remain.

This octahedron is supposed to rest on one of its planes, and the molecules *b c*, *c h*, *f c*, *c d*, may be conceived to constitute four of its edges.

In a similar manner the compatibility of the cubic molecule with the solids, obtained by Cleavage from the rhombic dodecahedron, might be easily shown.

Of Decrements, and the Characters of the Secondary Planes produced by them.

(69.) The explanation already given of the manner in which new planes modifying the primary forms may be conceived to be produced by the operation of different laws of Decrement, has been limited to the effect produced upon only a single edge or angle of the primary form. When similar edges or angles are all operated upon at the same time by any given Decrement, a new figure is produced.

The square prism has all its terminal edges similar, and all its terminal angles also similar, and, consequently, when one of those edges or angles is affected by any Decrement, they will generally all be so.

The upper part of fig. 48 will explain the manner in which a Decrement by one row of molecules on the terminal edges of a square prism, is conceived to produce a set of planes corresponding to those marked *c* of the tables of modifications. The lower part of the figure represents the ordinary character of the terminal planes of a square prism so modified.

The upper part of fig. 49 exhibits the effect of a Decrement by one row of molecules on the terminal angles of a square prism, producing a secondary form corresponding to the planes *a* of the modifications of that figure. The lower part presents the ordinary appearance of a square prism so modified.

(70.) The causes which occasion Decrements do not appear to be understood; Crystals so minute as to be seen only by the aid of a microscope, are found variously modified; hence the circumstance, whatever it may be, which occasions the modification, begins to operate very soon after the Crystal has been formed. Perhaps it may influence the arrangement of the first few molecules which are capable of producing a modified form; and as Crystals, during their increase in magnitude, sometimes undergo a change of form by the extinction of some modifying planes, or the production of others, the cause which occasions a Decrement may be suspended, or may be first brought into operation at any period during the increase of a Crystal in size.

For the purpose of affording a clearer illustration of the theory of Decrements, it has been found convenient to imagine that the primary form of any modified Crystal had attained such a magnitude before the law of Decrement had begun to act upon it, as to require for the completion of the Crystal in its modified state, the addition of only those defective plates of molecules by which the modifying planes might be produced. A primary form of this magnitude is evidently the greatest that could be inscribed in the given secondary form; and it is in theory termed the *nucleus* of the secondary form.

(71.) As far as we have proceeded with the theory of Decrements, the diminished plates of molecules have been supposed to be laid constantly upon the *primary* form, in order to produce the modifications which are found to exist in Nature. But it is probable that Decrements sometimes take place on secondary planes. Thus Decrements may be conceived to take place on any secondary rhomboid of carbonate of lime by the abstraction of small masses of primary molecules forming similar minute secondary rhomboids.

Decrements are sometimes related, as will appear in the next section, to the capacity of a body to become electric by heat, but it does not appear that any explanation has been given of the manner in which this influence is exerted.

Of the Law of Symmetry.

(72.) Among the definitions (11.) to (14.) will be found an explanation of *similar edges, angles*, and *planes* of a Crystal.

It has been ascertained from the observation of a great number of the secondary forms of Crystals, that when a modification takes place on any one edge or angle of any primary form, a similar modification generally takes place on all the similar edges or angles. And this has been observed to occur so frequently, as to induce the conclusion of its being the effect of a general law, which Haüy has called the Law of Symmetry. This law, however, does not act universally with regard to all such similar edges or angles as are included under the definitions already given. The tourmaline presents an instance of deviation from it. The primary form of the tourmaline is a rhomboid, and the three upper terminal edges, fig. 8, are *similar* to the three lower ones; the six lateral edges, as well as the six lateral solid angles, are also respectively *similar*. Yet it is found that the three upper terminal edges are sometimes truncated, while those below are not. It is also observed that sometimes only the alternate three of the lateral solid angles are modified, the three others remaining entire; but the tourmaline is pyro-electric, that is, capable of becoming electric by heat: and many other substances which are endued with a similar property, appear equally subject to a similar interference with the general Law of Symmetry.

But other minerals which are not pyro-electric, afford instances of deviation from strictly symmetrical modification; thus iron pyrites present a series of secondary forms which may be termed defective, when compared with those produced from the cube of galena. Pyro-electricity is not, therefore, the only disturbing cause which influences the deviation from the general Law of Symmetry in the formation of Crystals.

Of the Primary Forms of Crystals.

Of the Primary Forms of Crystals.

(73.) It has been stated that the selection of the form which is to be regarded as the primary, is in some degree arbitrary; and we might, as some other writers on Mineralogy have done, have assumed the cube, the regular tetrahedron, the regular octahedron, the rhombic dodecahedron, and the pentagonal dodecahedron, as distinct Primary Forms; under each of which, particular modifications of the cube might have been arranged. Or, we might, in consequence of the general relation which subsists among them, have referred all the modifications of the cube to either of these as the primary.

We might also have assumed either of the octahedrons arising from modification *a* or *c* of the square prisms as the Primary Forms of that system of Crystallization. And the same observation might be applied to the other classes of Primary Forms, it being demonstrable that any one of the forms so related to the others and to the primary, as these modifications are, might be adopted as the fundamental form of the system. But there would be a considerable difference in the facility with which the relations of the secondary forms to the primary could be explained in reference to some of these than to others. Those which are adopted in this

Treatise have been selected on account of the greater facilities they appear to afford for demonstrating those relations.

The Primary Form of every Crystal may be determined either from the primary or the secondary planes; or it may sometimes be deduced from cleavage, or from a consideration of both planes and cleavage. And in the remarks which will follow the tables of modifications, an explanation will be attempted of the manner in which the Primary Form of any crystallized mineral may be discovered.

Of the Secondary Forms of Crystals.

(74.) The Secondary Forms of Crystals differ from the primary in the number or position of their planes, and they are either *simple* or *compound*. The simple Secondary Forms are those which are produced by single modifications. The compound are those in which several modifications occur on one Crystal. The cube with the angles truncated or replaced by three or six planes, is an instance of a simple Secondary Form; but if the edges be also truncated, or bevilled, or the solid angle be both truncated and replaced by three or six planes, it will afford an example of a compound secondary form. These compound Secondary Forms are of very frequent occurrence among minerals.

(75.) The secondary planes frequently obliterate entirely the primary ones, and produce a *new figure*, as in the instance of the rhomboid being converted into a six-sided prism by the truncation of all its solid angles, or of its terminal solid angles and its lateral edges.

(76.) Particular Secondary Forms sometimes predominate in particular species of minerals, as an octahedron in sulphur, whose primary form is a right rhombic prism, and the regular hexagonal pyramid in quartz, whose primary form is a rhomboid.

A dodecahedral variety of carbonate of lime, commonly called dog-tooth spar, occurs the most frequently in Derbyshire.

In Cumberland, the most common variety is a six-sided prism terminated by the planes of an obtuse secondary rhomboid.

In the Hartz, the entire six-sided prism occurs more frequently than in other places. And we have noticed some Crystals from Plymouth which appear to have been originally of the form of the Derbyshire dodecahedrons, and to have been afterwards enlarged by additional particles, which have been so arranged as to convert the dodecahedrons into prisms similar to those from Cumberland. And in some Crystals, the points of the dodecahedrons are seen standing above the summits of the prisms.

Particular Secondary Forms are found to occur constantly among some species of minerals, and rarely among other species belonging to the same class of primary forms.

Thus the regular hexagonal pyramids, which occur constantly among the Secondary Forms of quartz and corundum, rarely occur in carbonate of lime.

The Secondary Forms of some minerals contain only half the number of modifying planes which the law of symmetry requires; as in the instance of the triangular planes on some Crystals of quartz which occur on only one side of the edge of the prism instead of being symmetrically placed on both its sides.

The causes of these peculiar habitudes of minerals are not known; and they appear to belong to that class of facts, which our limited knowledge of the operations of Nature does not enable us at present to comprehend.

Of Hemitrope and Intersected Crystals.

(77.) Besides the secondary forms referred to in the preceding section, there is another class which were termed *macles* by Romé de l'Isle, and by Haüy *hemitrope*, from their resemblance to Crystals which may be supposed to have been cut through, and one-half to have been turned partly round on an imaginary axis, passing through the centre of and perpendicular to the plane of section. The *imaginary axis* being termed the *axis of revolution*, and the *imaginary section* the *plane of revolution*.

This kind of structure may be readily understood from one or two examples.

(78.) If we conceive an octahedron, *a b c d e f*, fig. 50, to be cut through in the direction *g h* parallel to two of its planes; and if we suppose the half, *b d f*, partly turned round, as in fig. 51, until *b* is opposite to *c*, and *d* opposite to *e*, a Hemitrope Crystal would be produced, resembling one of the varieties of the common spinelle.

Again, if we suppose a doubly oblique prism, as in fig. 52, to be cut through in the direction *m n o*.

And if we then conceive one-half to be turned half round, as in fig. 53, we shall have a form of Hemitrope Crystal of frequent occurrence in cleavelandite.

These examples are sufficient to illustrate the manner in which Hemitrope Crystals might be conceived to be produced. The arrangement, however, of the molecules in so apparently capricious a manner, is doubtless the consequence of some law operating on the structure of the Crystal from the commencement of its formation, and analogous to those laws by which other secondary forms are produced.

Crystals of this character may occur among either unmodified primary forms, or secondary forms; the plane of the imaginary section being always parallel either to one of the primary planes, or to some secondary plane which would result from a regular decrement.

Oxide of tin, as shown in Mr. Phillips's Paper on that substance in the IId volume of the *Geological Transactions*, exhibits a considerable variety of forms of this nature. They are very common also in felspar, rutile, and sphene; and they occur in many other substances.

One character by which Hemitrope Crystals may frequently be known, is the re-entering angle which is produced by the meeting of some of their planes. This is very obvious in the figures 51 and 53. But even where this re-entering angle does not appear, there is generally some line, or some other character, which indicates the nature of the Crystal.

The term *twin Crystals* has been applied by some authors to denote these compound forms, upon the supposition that they are pairs of single Crystals united by particular planes.

(79.) Crystals are frequently found intersecting each other with greater regularity than can be ascribed to accident, and forming a class very analogous to Hemitropes, of which the staurotide affords a good example.

The primary form of the staurotide is a right rhombic prism, fig. 54.

Two of these prisms frequently cross each other at right angles, as in fig. 55. And sometimes at an oblique angle.

In other minerals it is sometimes observed, that three, four, or more Crystals intersect each other in this manner, and produce figures apparently remote in character from the primary forms to which they belong. Combined or intersecting Crystals frequently occur in arragonite, in carbonate of lead, in sulphuret of copper, and in other species of minerals.

Of Epigene and Pseudomorphous Crystals.

(80.) The crystalline forms already alluded to are supposed to be the proper forms of the mineral substances among which they occur. But minerals frequently present themselves under other, and what may be termed foreign, forms.

One class of these to which Haüy has applied the name of *Epigene*, consists of Crystals, the substance of which has undergone some chemical change subsequently to their formation.

Thus Crystals of blue carbonate and of red oxide of copper are frequently found converted into green carbonate. Sulphuret and carbonate of iron are changed into oxides, without losing their peculiar crystalline forms; and the same alteration takes place in other minerals.

(81.) Another class of Crystals whose forms are also foreign to the substances in which they occur, have been denominated *Pseudomorphous.* These have been formed either *within cavities* from which Crystals of some other substance have been previously removed by some natural cause, or *upon* Crystals of some other substance, which Crystals have subsequently disappeared; the space they occupied either remaining void, or being found filled with some other matter.

Both these classes of Crystals, particularly the first, may occasion some embarrassment to the young Mineralogist, but this will be lessened by an improved acquaintance with the minerals in which they occur.

The theory of the formation of Pseudomorphous Crystals presents however some difficulties which it does not seem easy to remove. It is not easy to conceive how the Crystals, resembling in their figure those of quartz and carbonate of lime, which are found in what is termed crystallized steatite, could have been formed. The Crystals themselves and the mass in which they are imbedded being apparently composed of homogeneous matter.

Of the Phenomena of Crystallization.

(82.) Little is at present known concerning the nature of those forces or influences which determine mineral bodies to assume crystalline forms, or concerning the causes which produce such a diversity of those forms. Haüy says, that "when the molecules of a body are suspended in a fluid, which afterwards, either by evaporation, or through some other cause, abandons them to their reciprocal affinities, if no disturbing force should interfere, the molecules would unite by those planes the most disposed to such union, and would by their combination produce the regular solids which we term Crystals."

But this explanation of the manner in which a change of state from solution to solidity may take place, does not assist our inquiry into the causes which predispose the molecules to form solids of particular shapes; or why their mutual attractions should cease in particular directions, as in the formation of a cubic Crystal, which is defective at all its solid angles.

Of the Phenomena of Crystallization.

The causes of Crystallization are probably allied to electricity, whose relations are much more extensive than they were formerly supposed. We shall not, however, enter further upon this subject, but shall briefly inquire into the general phenomena of the production of Crystals.

(83.) The different hypotheses which assign an aqueous, or an igneous origin to what has been termed the crust of our earth, suppose the minerals forming that crust to have been produced by analogous causes.

It is however certain that many of the natural Crystals with which we are acquainted, were not formed contemporaneously with the beds in which they have been discovered; but that they have been produced at later periods, and possibly under very different circumstances. Sometimes their origin may be ascribed to the action of heat, sometimes to the solvent power of some fluid, and in other instances to the united influence of both these causes.

The observations of Sir Humphrey Davy "Upon the state of water and aeriform matter in cavities found in certain Crystals," printed in the *Philosophical Transactions* for 1822, render it not improbable that natural Crystals are formed under very different degrees both of pressure and temperature. There are several appearances not uncommon among Crystals, from which it may be inferred that they are sometimes very slowly formed, and that accompanying Crystals of different minerals have been deposited at very different periods.

The Crystals of carbonate of lime which are found at Ecton in Staffordshire, frequently contain numerous minute Crystals of copper pyrites, apparently first deposited on small Crystals of the carbonate of lime. This substance has then formed over the pyrites, and produced a larger Crystal of carbonate of lime, upon which a second deposit of copper pyrites has taken place. This has been again enclosed within a still larger Crystal of the calcareous matter, upon which other Crystals of pyrites have been again deposited. And we may discover, when the Crystals are large, many alternations of these two minerals successively covering each other.

The Crystals which are termed pseudomorphous sometimes afford very distinct evidence of successive formation, as the period at which these were produced must have been posterior to that of the Crystals whose forms they imitate. We have observed in one instance a mould in preparation, if we may so term it, for a pseudomorphous Crystal, from which a part only of the model, a cube of fluate of lime, had been removed, leaving in the cavity only a small loose nodule with an irregular and smooth surface like that of partially dissolved salts.

Hollows of various forms contained within crystallized quartz are not uncommon; but we do not recollect any other instance of the Crystal, whose removal had produced the vacuity, being only in part destroyed, as if its dissolution had been recently going on. Numerous other examples might be cited as evidences of the gradual formation of Crystals, by processes which are probably still in operation, although we are uninformed respecting their nature.

There are circumstances which render it almost certain that some Crystals have been produced from solution in a fluid. The water found in the cavities of certain Crystals of quartz, would seem to refer their origin to

solution in that fluid; and it is known from the copious deposit of silicious matter from the waters of the Geyser in Iceland, and from the hot springs in the Island of St. Michael's, that quartz may be held abundantly in solution by water.

Whether the metals have been deposited from chemical solutions, or from a state of fusion, are points upon which no certain information has been obtained, nor do the few facts which are known throw much general light on the subject.

Some specimens brought from Torre del Greco have been described by Mr. Aikin in the *Geological Transactions*, among which were some minute octahedral Crystals of red oxide of copper attached to the surface of a fused and partly oxidated mass of copper and iron. These must have been produced by sublimation of the particles which composed them.

It appears from a Paper by Dr. Wollaston published in the *Philosophical Transactions* for 1823, that the metallic titanium which he discovered among the slags from some iron-works, is wholly infusible; but he conjectures that it might have been precipitated in its present crystalline forms in the state of oxide, in which it might have been sublimed. And in this manner Crystals of the metals and their ores may possibly have been deposited upon quartz, or upon other earthy substances.

The red oxide of mercury produces sometimes very distinct Crystals by sublimation. And Crystals of calomel and of other substances may be produced in a similar manner.

(84.) The processes of the laboratory are the only means we possess of investigating the phenomena of Crystallization. Some minute Crystals of quartz are said to have been deposited from an alkaline solution of that substance after long standing; and Crystals of carbonate of lime have been observed in vessels which contained the elements of that mineral in solution. Lead may be produced in thin metallic plates from the decomposition of acetate of lead by metallic zinc. Bismuth, antimony, and some other metals may also be made to crystallize by fusion; but these few facts afford no conclusions explanatory of the natural processes of metallic Crystallization. Many experiments have, however, been made with a view to investigate those processes, from which several curious and interesting results have been obtained.

Most bodies have a tendency to crystallize in passing from a state of fusion or solution into a solid state. Water may be said to crystallize at 32° of Fahrenheit, although it does not exhibit regular cleavage planes when broken, and flakes of snow frequently exhibit regular and beautiful forms. Highly concentrated acetous acid becomes solid and assumes a crystalline form at about 50° of Fahrenheit: and mercury crystallizes at about 72° below the freezing point of water, and when in a solid state it is brittle and exhibits a distinct crystalline fracture if broken. Lead, antimony, and most other metals, become fluid at different temperatures above that of boiling water, and when suffered to cool gradually, they may be brought to crystallize with more or less regularity. For this purpose they are to be melted in deep vessels, and when the metal has become solid at the surface by slow cooling, that surface is to be broken, and the metal which remains fluid within, being poured out, the hollow will frequently be found lined with very regular Crystals.

Among the slags from furnaces regular Crystals frequently occur, not only of metallic but of earthy substances.

Of the Phenomena of Crystallization.

(85.) The artificial production of Crystals from solution in a fluid may be considered in reference to the circumstances attending their deposition, to their size, their forms, whether simple or compound, regular or irregular, and to the characters of their planes.

(86.) The variations in the temperature and hygrometric state of the air, but more particularly the latter, will influence the deposition of Crystals. When the air is dry, evaporation proceeds more rapidly, and Crystals are then deposited more freely. Heat, as it promotes evaporation, predisposes a solution to deposit Crystals, which are generally best formed when the evaporation has been slow, and as the solution cools.

But Crystals are not always deposited when even a saturated solution cools.

If a concentrated solution of sulphate of soda be enclosed while hot in a tube, it will not deposit Crystals on cooling; but if air, or gas of any kind, be admitted to it, the whole mass becomes almost instantaneously solid.

(87.) There is a considerable diversity in the manner in which the Crystals of different salts are deposited. Sometimes they stand singly on the bottom of the vessel containing the solution. In other instances their tendency is to form into groups, the Crystals of which appear sometimes to radiate from a common centre. This character is very conspicuous among natural Crystals in wavellite, in some varieties of sulphate of lime, arseniate of cobalt, and other minerals. The Crystals of sulphate of magnesia, of rhombic sulphate of nickel, of nitrate of potash, and many other substances, if rather rapidly produced, form long slender prisms, which so intersect each other as to lie in almost every direction. Carbonate of magnesia does not crystallize, if the quantity dissolved be small, until the bulk of the solution be nearly equal to the bulk of the Crystals that are produced from it. And the solutions of other salts are known to require a high degree of concentration before they will deposit any Crystals.

(88.) The nature of the surface of the vessel containing the solution will influence the precipitation of Crystals. Thus Crystallization is said to take place more rapidly in rough earthenware than in glass vessels, and it is well known that threads, horse-hair, fine wire, sticks of glass, and other foreign bodies introduced into a solution will be covered with Crystals in preference to the surface of the containing vessel.

When a solution is ready to deposit Crystals, they will be immediately produced if a fragment of the substance dissolved be introduced into it. And however irregular the shape of this fragment may be, the irregularities will be found to disappear as it increases in bulk, and a regular Crystal will be produced, which will be enlarged as the evaporation proceeds.

(89.) The size of the Crystals is generally influenced by the volume of the solution and by its depth. When the volume and depth are considerable and the evaporation slow, large Crystals will generally be formed. But in operating upon small quantities of fluid, Crystals of different sizes are frequently produced in the same vessel, and in apparently a capricious manner. And it has been said, that solutions charged with electricity have deposited smaller Crystals than when in their natural state.

Some salts, of which the sulphate of copper and

nickel, and the sulphate of copper and zinc are examples, deposit much larger Crystals during the cooling of a smaller quantity of a saturated hot solution, than from the spontaneous evaporation of a much greater volume at the actual temperature of the atmosphere.

(90.) With regard to the forms of Crystals, those which are considered primary rarely occur among either natural or artificial Crystals, nor has experiment yet pointed out any means by which these may with certainty be produced.

It has been said, that more simple forms are produced when an impalpable powder is mixed with the solution of a salt.

There does not, however, appear to be much constancy in the result of such experiments, but on the contrary different substances appear to possess peculiar habitudes in this respect and not to exhibit corresponding results.

Chemical mixtures influence the forms of Crystals, perhaps more frequently than any other cause, yet in a manner of which we believe at present no clear conception can be formed. Mr. Brochant remarks, with great justice, that the nature of this influence is a highly important point in the History of Crystallization, as it is probable that it very frequently governs the formation of natural Crystals. Some chemical mixtures appear to influence even the primary forms of Crystals, without apparently altering the nature of their chemical constitution, while others merely occasion changes in the modifications of those forms. Thus sulphate of nickel, if crystallized from an acid solution, takes a square prism as the primary form; but if the square prisms thus obtained be dissolved in water and re-crystallized, rhombic prisms are produced, without any apparent atomic difference in the proportions of their respective elements.

The difference between the forms of carbonate of lime and arragonite, which are probably similar chemical compounds, may have resulted from some interference analogous to this; and we may, perhaps, refer to the same cause the difference of figure between the common and the white iron pyrites.

(91.) The faces on which Crystals deposited from solutions rest, are generally extended disproportionately in relation to the other planes. But this is not invariably the case, nor does the position of the deposited Crystal in the solution always influence its figure.

If the crystalline particles were constantly more numerous towards the bottom of the solution than at its surface, it might be supposed that Crystallization would first take place at the bottom, and that the lower planes of immersed Crystals would be the most enlarged; and this is frequently found to be the case.

But several of the salts begin to crystallize almost invariably at the surface; and while the Crystals thus formed sink and increase in size at the bottom, others are successively produced above.

We have remarked also among some Crystals of nitrate of lead, which were deposited together in the same vessel, some which were unmodified octahedrons, and others that were hemitropes. Of the octahedrons, some had their axes perpendicular to the surface on which they rested; others rested on one of their planes; and others were attached by an edge to the bottom of the vessel; a variety of position which excludes the idea of its being the result of any particular law.

The natural planes of Crystals are subject to a considerable diversity of character, some possessing the highest degree of brilliancy, and others being so dull as to afford no distinct reflections. Sometimes they are striated, sometimes curved, and they commonly exhibit greater or less degrees of inequality. Particular planes of some Crystals are frequently marked by some distinguishing peculiarity which occurs also on the corresponding planes of other Crystals, of the same substance. Thus the planes which truncate the primary terminal edges of the Crystals of carbonate of lime are generally striated parallel to their edges of combination; and the terminal planes of hexagonal prisms of that substance are generally opaque and dull.

Among artificial Crystals a difference is frequently observable in the characters of the planes, but it is not constant even under analogous circumstances. Sometimes the most perfect planes appear on those Crystals which have been slowly formed, and sometimes on those which have been rapidly produced, particularly in some of the double salts. We have repeatedly tried to obtain by slow evaporation Crystals of the sulphate of copper and zinc with bright planes, but without success; yet they have been immediately produced on the cooling of a hot saturated solution, and we have observed more perfect Crystals of sulphate of copper produced in this manner than from slow evaporation.

It must, however, be admitted that these experiments and facts do not afford the desired illustration of the natural processes of Crystallization.

Of the Tables of Modifications.

(92.) Crystals of different minerals may belong to the same system of Crystallization. Thus fluate of lime and sulphuret of silver are both referable to the cube. Carbonate of lime and red silver are both rhomboids. Sulphate of lead and hydrous oxide of iron are both right rhombic prisms. And so of other minerals.

When several species are related to one system, or, as we shall henceforth express ourselves, to one class of primary forms, they will, unless that class be the cube, generally be found to differ from each other, in the mutual inclination of their primary planes, or in the comparative lengths of some of their primary edges.

(93.) Crystals rarely present themselves under their respective primary forms, but are usually modified by new planes, producing secondary Crystals, from which the primary are to be inferred. Hence an accurate knowledge of the relations between the secondary and primary forms of Crystals is essential to a correct crystallographical discrimination of minerals.

The secondary forms of Crystals have been explained to consist of Modifications of the primary, occasioned by decrements on some of their edges or angles, the laws of which will be afterwards investigated. But as there are many who form collections of minerals as an amusement, and others who pursue some branch of Mineralogy as a business, and who from want of inclination, or leisure, or a habit of engaging in such inquiries, are disinclined to undertake a geometrical investigation of the relations of Crystals, we have attempted to supply another method of exhibiting those relations in the following Tables of Modifications of the primary forms, and the explanations which follow them. And although these may not furnish the Mineralogist with all the assistance he requires, his study of Crystals will be

materially assisted by the opportunity they will afford him of comparing all the primary and simple secondary forms with each other, and of obtaining a general view of the entire series of simple secondary forms under which Crystals may present themselves. And as the most compound secondary forms are only combinations of two or more simple Modifications, these Tables will explain the most complicated figures of Crystals.

(94.) The Tables contain not only the *observed* Modifications of Crystals, but the entire series of which each class of the primary forms is susceptible while influenced by the law of symmetry, with the addition of some of the observed instances of departure from this law in the production of what may be termed incomplete secondary forms.

From a general view of the Tables, it will be seen that the first Modifications are those on the angles of the primary form; these being succeeded by the Modifications on the edges; beginning in all cases with the simplest change of form.

It has been already stated, that each class of the primary forms may comprise many series of Crystals belonging to as many different species of minerals. And in the same manner each of the Modifications, excepting those which produce tangent planes, may include a number of individual or particular planes differing from each other in the angles at which they respectively incline on the adjacent primary planes.

Thus a series of modifying planes comprehended under *b* in the Modifications of the cube may occur within two natural limits; the one the primary plane of the cube, and the other the plane *a*. For it is obvious that the inclination of *b* on P may approach nearly to 180°, but it can never reach that limit. And it may pass from this position through perhaps an unlimited series inclining less and less on P, until at length the inclination would be nearly the same as that of *a* on P; but it is apparent that it can never attain this limit, there being no other plane than *a* which can incline to the primary planes at the same angle that *a* does.

The series of planes belonging to Modification *c* of the cube, are limited within the planes *a* and *c*. The angle at which the planes marked c incline to each other, may be conceived to increase, until it approaches very nearly to 180°; the three planes would then very nearly become one, or be nearly similar to *a*, but they can never reach that limit. And they may also be conceived to incline more and more upon the edge, until at length they would very nearly coincide with the planes *e*, but they could never exactly coincide with those planes.

The series of particular Modifications of the cube comprehended under *d*, may be conceived to lie within several limits, according to the direction in which the change of position of the modifying planes may be supposed to take place. The angle at which the two planes *d*, which rest on P′, incline to each other may be imagined to increase until they nearly approach to one plane, corresponding with *b*, or the angle at which the two planes *d*, which meet at the edge of the cube, incline to each other, may approach nearly to 180°, when they would nearly become analogous to *c*. Or if the two planes *d*, which meet at the edge of the cube, be conceived to incline more and more on that edge, they will at length approach nearly to the position of the planes *f*, but they can never coincide with those planes.

These remarks on the nature of the differences among the planes belonging to some of the Modifications, might easily be extended to all. But it will not be difficult for the reader to apply them himself to all the other variable ones. The nature of the variation, however, will occasionally be pointed out in the Tables.

(95.) When the new planes which would result from any particular Modification are so much extended as to efface the primary planes, a new solid will evidently result. The series of new solids which might result from any single Modification, will be found generally to possess one common character: that is, their planes will generally be all triangular, or all quadrilateral, or all pentagonal, or some other common figure; but this is not invariably so. Among the series of secondary forms resulting from particular Modifications of the rhomboid, some will be contained within scalene triangular planes, and others belonging to the same Modification within isosceles triangular planes, as will be pointed out in the Tables.

(96.) A particular position is chosen in these Tables for the figure of each of the primary forms, and the same is retained in the series of Modifications.

The right rhombic prism is supposed to have its greater diagonal horizontal.

In the oblique rhombic and doubly oblique prisms the angles of P with M and T are supposed to be obtuse; and if the figures of Crystals of different substances belonging to the same class of primary forms, were always placed in the same positions as those in the Tables, they might more easily be compared with each other, and their peculiar characters be more readily described.

(97.) On each of the primary forms certain letters are placed, which are intended to designate the angles, edges, and planes of Crystals, and to denote their similarity or dissimilarity.

Some or all of the vowels A E I O are used to designate the *plane angles* of the primary form; some of the consonants, B C D F G H, to designate the *primary edges*, and P M T the *primary planes* of Crystals.

The same letter is repeated where the angles, edges, or planes are similar; and different letters are used where those angles, edges, or planes are dissimilar, according to the definitions of similar angles, &c., already given (11.) to (14.)

Thus the letter A is repeated on the four angles of the cube, these being all similar; while A and E are placed on the alternate angles of the right rhombic prism to show that in that figure those angles only are similar which are opposite to each other.

In the cube the letter P is repeated on all the planes, because they are all similar.

In the right rhombic prism the letter P stands on the terminal plane, and M on the lateral planes, implying that these are not similar to the terminal plane; but M being repeated on both the lateral planes, denotes that these are similar to each other. When M stands on one and T on the other, they are dissimilar.

The ′ and ″, (which are to be read dash and two dash,) added to some of these letters, serve merely to distinguish two or more similar edges, angles, or planes from each other.

By carefully observing the letters thus used to designate the planes, &c., the class of primary forms to which any figure, drawn according to this method, belongs, may be readily discovered.

When the planes of a Crystal are parallel, if taken

Crystallography.

in pairs, not more than one half of their number can be rendered visible in the front of the drawing; but when the planes are not all parallel, as in the tetrahedron, more than half may be exhibited according to the position of the Crystal. For it is evident that if the tetrahedron be held with a solid angle nearest to the eye, three of its four planes will be seen at the same time.

It may be remarked that the modifying planes contained in the Tables, are produced by cutting off portions of the figure of the primary Crystal, and thus reducing its bulk. It is almost unnecessary, after what has been already said on the formation of Crystals, to observe, that nature proceeds by building up the secondary forms instead of thus truncating the primary. And we may, if we please, imagine that the secondary figures given in these Tables, have been produced by additions to primary Crystals of smaller relative dimensions.

The inclination of any two planes to each other, as P, and Modification a of the cube, or the angle at which they meet, may be expressed by P on a, or a on P, or simply by P,a, or a,P, adding the value of the angle in degrees and minutes.

Tables of the Primary Forms and their Modifications.

THE CUBE.

Fig. 56.

(99.) *Mod. a*, fig. 57. The solid angles replaced by tangent planes, whose surfaces are equilateral triangles.

When the modifying planes are extended so as to efface the primary planes, a regular octahedron is produced.

$$P,a = 125^\circ\ 15'\ 52''$$
$$a,a' = 109^\circ\ 28'\ 16''$$
$$a',a'' = 70^\circ\ 31'\ 44''$$

Mod. b, fig. 58. The solid angles replaced by three planes resting on the primary planes.

From this Modification a series of new figures might result, each of which would be contained within twenty-four equal trapezoidal planes; the trapezoids being dissimilar in the different members of the series, and inclining at different angles on the primary planes and on each other. The different members of every other series of new figures which can result from any Modification of this or any other Primary Form will *generally* agree in the character of their planes, but these will always differ in their inclination to the primary and to each other. An observation which it will not be necessary to repeat in reference to any series belonging to any other of the Primary Forms.

Mod. c, fig. 59. The solid angles replaced by three planes resting on the primary edges.

New figures contained within twenty-four equal isosceles triangular planes.

Mod. d, fig. 60. The solid angles replaced by six planes.

New figures contained within forty-eight triangular planes.

Mod. e, fig. 61. The edges replaced by tangent planes.

New figure the rhombic dodecahedron.

$$P,e = 135^\circ$$
$$e,e' = 120^\circ$$

Mod. f, fig. 62. The edges replaced by two planes.

New figures contained within twenty-four triangular planes.

Tables of the Primary Forms and their Modifications.

(100.) Some of the forms assumed to be derived from the cube, contain only half the number of modifying planes which the law of symmetry requires. Of these there are two different sets. One belonging to the tetrahedron, the other to a pentagonal dodecahedron; and as these are the predominating figures of some species of minerals, it will be convenient to denote their relations to the cube in the following manner.

In fig. 63 the planes a appear only on the *alternate* solid angles, and present only half the number of planes required by the law of symmetry. The figure may therefore be denoted by *Mod.* $\frac{a}{2}$. When these planes are so much extended as to efface the primary planes, a regular tetrahedron would be produced, as shown by the lines on the figure. And it is evident that this same form would be produced, but in a transverse position, if the modifying planes were placed on those angles which are entire on the figure.

The planes b, c, and d occur also on the *alternate* solid angles, and may be denoted by $\frac{b}{2}$, $\frac{c}{2}$, and $\frac{d}{2}$. It is evident that the planes of this class of hemi-forms, as they may be termed, are not parallel, but inclined to each other; a character by which they may be distinguished from the following.

(101.) When the cube is modified by only twelve of the planes of *Mod. f*, as shown in fig. 64, a series of pentagonal dodecahedrons will be produced, contained within six pairs of *parallel* planes. The relation of this figure to figure 62, is seen by the corresponding letters on the planes of each. This class may, on account of the *parallelism* of its planes, be denoted by $\frac{f}{2}\,\|$, and as three only of the six planes of *Mod. d* sometimes occur on each solid angle, these may be denoted by $\frac{d}{2}\,\|$. The addition of $\|$, the symbol of parallelism, being sufficient to distinguish these from the planes already denoted by $\frac{a}{2}$, $\frac{b}{2}$, $\frac{c}{2}$, and $\frac{d}{2}$.

THE SQUARE PRISM.

Fig. 65.

(102.) The Crystals of different minerals belonging to this class may differ from each other in the comparative lengths of the edges B and G.

Mod. a, fig. 66. The solid angles replaced by single planes which are isosceles triangles.

This Modification would produce a series of four sided pyramids, resting on the lateral edges of the prism. And when the modifying planes are so much enlarged as to efface the primary, a series of octahedrons with square bases will result.

The planes a incline equally on M and M′, but at a different angle from that at which they incline on P. A character by which this form is distinguished from the cube, where a inclines equally on the adjacent primary planes.

Mod. b, fig. 67. The solid angles replaced by two planes.

The new figures are bi-pyramidal, and contained within sixteen sides.

(103.) The two planes of this Modification may intersect the planes M, M′, parallel to a diagonal or other-

wise, according to the nature of the decrement by which they are produced.

When both planes occur on a Crystal, and intersect M and M′ parallel to a diagonal, it will be convenient to denote them by the character $b_{\prime\prime}$ and the series of such planes may be distinguished by $b_{\prime}1$, $b_{\prime}2$, $b_{\prime}3$, &c. When they result from intermediary decrements, and consequently do not intersect M or M′ parallel to a diagonal, they may be denoted simply by *b*.

If only one of the two planes *b* should appear on the Crystal, it may be denoted by $\frac{_{\prime}b}{2}$ or $\frac{b_{\prime}}{2}$, if parallel to a diagonal on the left or right of the figure, and by $l\frac{b}{2}$ or $\frac{b}{2}r$, if not parallel to a diagonal.

The same observations will apply to the planes *b* and *d* of the right and oblique rhombic prisms.

Mod. c, fig. 68. The terminal edges replaced by single planes not forming equal angles with the terminal and lateral planes, producing a series of four-sided pyramids resting on the lateral planes of the prism, and, by an extension of the modifying planes, a series of octahedrons with square bases.

Mod. d, fig. 69. The edges of the prism replaced by tangent planes.

Mod. e, fig. 70. The edges of the prism replaced by two planes.

The separate Modifications of the terminal edges, or the lateral edges, will distinguish the secondary Crystals of this class of prisms from those of the cube.

THE RIGHT RHOMBIC PRISM.

Fig. 71.

(104.) The solid angles at A are the *obtuse*, and those at E the *acute* solid angles. The edge G is the *acute*, and H the *obtuse* lateral edge of the prism.

The particular prisms belonging to different minerals may differ from each other in the inclination of M on M′, or in the ratio of the edge B to the edge H.

Mod. a, fig. 72. The obtuse solid angles replaced by single planes which intersect the terminal plane parallel to its greater diagonal.

When the planes *a* increase, the secondary form may be an octahedron with a rectangular base, as shown in fig. 73.

Mod. b, fig. 74. The obtuse solid angles replaced by two planes.

This Modification would produce a series of four-sided pyramids, and the new figures would be octahedrons with rhombic bases.

Mod. c, fig. 75. The acute solid angles replaced by single planes, which intersect the terminal plane parallel to its short diagonal.

An octahedron with a rectangular base, as shown in fig. 76, might result from this Modification.

Mod. d, fig. 77. The acute solid angles replaced by two planes.

The new figures would be octahedrons with rhombic bases.

The planes *b* and *d* may be denoted as in the square prism.

Mod. e, fig. 78. The terminal edges replaced by single planes.

This Modification would produce a series of four-sided pyramids, and the new figures would be octahedrons with rhombic bases.

Tables of the Primary Forms and their Modifications.

Mod. f, fig. 79. The obtuse lateral edges replaced by tangent planes.

Mod. g, fig. 80. The obtuse lateral edges replaced by two planes.

When the primary lateral planes are effaced by the planes *g*, a series of secondary Right Rhombic Prisms would be produced.

Mod. h, fig. 81. The acute lateral edges replaced by tangent planes.

Mod. i, fig. 82. The acute lateral edges replaced by two planes.

This Modification would produce another series of secondary prisms.

THE OBLIQUE RHOMBIC PRISM.

Fig. 83.

(105.) The figure is supposed to be oblique in the direction O A, so that the terminal plane forms an obtuse angle with the edge H. The planes M M′ may meet at an acute, or an obtuse angle. The solid angle at A is in either case termed the *acute*, and that at O the *obtuse*, and those at E the lateral solid angles.

The edges B are the *acute*, and those at D the *obtuse* terminal edges. The edge H and its opposite are the *oblique*, and G and G′ the *lateral* edges of the prism.

The Crystals of this form belonging to different minerals may differ from each other in the inclination of P on M, or of M on M′, or in the ratio of an edge D to an edge H.

Mod. a, fig. 84. The obtuse solid angles replaced by single planes.

Mod. b, fig. 85. The obtuse solid angles replaced by two planes.

Mod. c, fig. 86. The acute solid angles replaced by single planes.

Mod. d, fig. 87. The acute solid angles replaced by two planes.

The planes *b* and *d* may be denoted as in the square prism.

Mod. e, fig. 88. The lateral solid angles replaced by single planes.

(106.) The planes of this Modification may cut the terminal or lateral planes parallel to a diagonal, or otherwise according to the decrement by which they are produced. If *e* cuts the terminal plane parallel to a diagonal, it may be denoted by $\bar{e}$; if the plane ∥ M′ by $_{\prime}e$; and if the plane M, by $e_{\prime}$. And a corresponding notation may be applied to the planes *a*, *b*, *c*, and *d*, of the doubly oblique prism.

Mod. f, fig. 89. The obtuse terminal edges replaced by single planes.

Mod. g, fig. 90. The acute terminal edges replaced by single planes.

Mod. h, fig. 91. The oblique edges of the prism replaced by tangent planes.

Mod. i, fig. 92. The oblique edges of the prism replaced by two planes.

Mod. k, fig. 93. The lateral edges of the prism replaced by tangent planes.

Mod. l, fig. 94. The lateral edges of the prism replaced by two planes.

Mod. i and *l* would produce other Oblique Rhombic Prisms, varying from the primary and from each other, in the angles at which their lateral planes would meet.

This class of prisms may generally be distinguished from rhomboids by the unequal inclination of the plane *c* to three adjacent primary planes, and by the dissimilarity of the planes *f* and *h*, or *g* and *k*.

THE DOUBLY OBLIQUE PRISM.

Fig. 95.

(107.) In this class of prisms the inclinations of P on M, P on T, and M on T, are all different.

The edges and angles of these prisms may be designated by the same terms as have been used for the corresponding ones of the oblique rhombic prism.

The different Crystals belonging to this class may differ from each other in the inclination of P on M, P on T, and M on T, and in the ratios of the edges D, F, and H.

Mod. a, fig. 96. The obtuse solid angles replaced by single planes.

Mod. b, fig. 97. The acute solid angles replaced by single planes.

Mod. c, fig. 98. The lateral solid angles E replaced by single planes.

Mod. d, fig. 99. Lateral solid angles I replaced by single planes.

Planes *a*, *b*, *c*, and *d* may be denoted similarly to those of *Mod. e* of the oblique rhombic prism.

Mod. e, fig. 100. The obtuse terminal edges D replaced by single planes.

Mod. f, fig. 101. The acute terminal edges C replaced by single planes.

Mod. g, fig. 102. The acute terminal edges D replaced by single planes.

Mod. h, fig. 103. The obtuse terminal edges F replaced by single planes.

Mod. i, fig. 104. The oblique edges of the prism replaced by single planes.

Mod. k, fig. 105. The lateral edges of the prism replaced by single planes.

From the dissimilarity of any two adjacent edges or angles of this class, the separate Modifications produce only single planes; but several varieties of these may occur on the same edge or angle. The secondary forms belonging to this class, are among the most difficult Crystals to be understood.

THE RHOMBOID.

Fig. 106.

(108.) The angle at T is the *superior*, that at O the *inferior*, and those at E the *lateral* angles of the plane P. The edges B are the *superior*, and those at D the *inferior* edges of the same plane.

The solid angle at A is the *terminal*, and those at E and O are the *lateral* solid angles. The edges B are the *terminal*, and D the *lateral* edges of the Rhomboid.

Rhomboids are distinguished from each other by the inclination of P on P′. When P on P′ measures more than 90°, the Rhomboid is called obtuse; when less it is called acute.

Mod. a, fig. 107. The terminal solid angles replaced by tangent planes.

Mod. b, fig. 108. The terminal solid angles replaced by three planes resting on the primary planes.

Mod. c, fig. 109. The terminal solid angles replaced by three planes resting on the primary edges.

Each of the Modifications *b* and *c* would produce a series of Rhomboids more obtuse than the primary; but differing in their relative positions.

Tables of the Primary Forms and their Modifications.

Mod. d, fig. 110. The terminal solid angles replaced by six planes. The new figures are obtuse dodecahedrons whose planes are generally scalene triangles.

Mod. e, fig. 111. The lateral solid angles replaced by single planes *parallel to the axis* of the Rhomboid.

These planes are the lateral planes of a regular hexagonal prism.

Mod. f, fig. 112. The lateral solid angles replaced by two planes, whose edge of intersection is parallel to the axis of the Rhomboid.

These planes represent the lateral planes of a series of dodecahedral prisms.

Mod. g, fig. 113. The lateral solid angles replaced by single planes intersecting the primary planes *parallel to their oblique diagonals.*

The new figure would be a Rhomboid more acute than the primary.

Mod. h, fig. 114. The lateral solid angles replaced by two planes intersecting the primary planes *parallel to their oblique diagonals.*

The new figures would be acute dodecahedrons, whose planes are generally scalene triangles.

Mod. i, fig. 115. The lateral solid angles replaced by single planes which *intersect the primary planes in lines that converge towards the summits.*

The new figures would be Rhomboids, more acute than the primary.

Mod. k, fig. 116. The lateral solid angles replaced by two planes, which intersect the primary planes similar to *Mod. i.*

The new figures are generally acute dodecahedrons with scalene triangular planes.

Mod. l, fig. 117. The lateral solid angles replaced by single planes, *whose intersection with the primary planes converge toward the inferior angles.*

This Modification produces Rhomboids more acute than the primary, but in an inverse position to those of *Mod. i.*

Mod. m, fig. 118. The lateral solid angles replaced by two planes, whose intersections with the primary planes are similar to those of *Mod. l.*

The new figures are acute dodecahedrons, generally with scalene triangular planes, and in an inverse position to those of *Mod. h* or *k*.

Mod. n, fig. 119. The terminal edges replaced by tangent planes producing a Rhomboid more obtuse than the primary.

Mod. o, fig. 120. The terminal edges replaced by two planes.

The new figures are obtuse dodecahedrons, whose planes are generally isosceles triangles.

Mod. p, fig. 121. The lateral edges replaced by tangent planes.

Planes *p* are the lateral planes of a regular hexagonal prism.

Mod. q, fig. 122. The lateral edges replaced by two planes.

From this Modification there results a series of dodecahedrons, whose planes are always scalene triangles.

Some of the Modifications of the Rhomboid and the secondary forms which they produce, bear a general resemblance to those of the oblique rhombic prism, as will be readily perceived by comparing *Mod. a* of the prism with *a* of the Rhomboid. And by respectively comparing *g* and *f* of the prism with *n* and *p* of the Rhomboid.

But these forms may be distinguished by the equal inclination of *a* of the Rhomboid on the three adjacent planes; or by the simultaneous Modification of the three terminal or six lateral edges of the Rhomboid.

When the primary planes of the Rhomboid are effaced by secondary planes, it is only by observing the direction of the cleavage planes, or some other determinate character, that the Modification to which the secondary figure belongs can be ascertained.

Of the Application of the preceding Tables.

(109.) The preceding Tables and remarks will have afforded the reader such a general outline of the relations among the several primary and secondary forms of Crystals, as will enable him in very many cases to determine at once the primary form and modification of any given Crystal. But he may not be enabled to do this generally without some further explanation of the method of what may be termed *reading* Crystals.

The practical use of Crystallography is, as we have before stated, to enable the Mineralogist to determine the species of a mineral from an examination of its crystalline forms.

These forms are either primary or secondary; they are frequently very complicated; and the Crystals from which they are to be determined, are generally only fragments detached from the matrix on which they have been produced, and are occasionally very imperfect.

(110.) The regular symmetry of the secondary forms of the *cube* is such as to admit little doubt concerning the primary in those cases where the secondary planes can be distinctly recognised. But the planes *a* of the regular octahedron are not always distinguishable from those of *Mod. a* of the square prism, without measurement.

(111.) The secondary forms of the *square prism* may generally be distinguished from those of the cube by the want of simultaneous and similar Modifications on the lateral *and* terminal edges, and by the difference of measurement between the octahedrons derived from it and the regular octahedron.

(112.) When there is only a single set of cleavages parallel to the lateral planes of a square prism, the planes parallel to the cleavage are assumed to be the primary. If there are two sets of cleavages, parallel to the planes M and *d*, either of these might be considered the primary set; and in respect of any Crystals already described we can only ascertain which set has been assumed as the primary by a comparison of the Crystals themselves with the published descriptions and figures.

(113.) The *right rhombic prism* presents very little analogy to either of the preceding forms, unless the inclination of the lateral planes upon each other is very nearly a right angle. The octahedrons which might then result from *Mod. e* would nearly resemble those of the square prism, as the inclination of e on e' would be nearly the same as that of e' on e''. But the rhombic prism may then be distinguished from the square prism by either of the *Mods. f* or *g* or *h* or *i* appearing singly on the Crystal.

There is sometimes a cleavage corresponding to the position of the planes M, M′, in Crystals belonging to this form, in which case those planes are determined from the cleavage. But occasionally the only apparent cleavages are parallel to *f* or *h*, in which case the planes, which are to be regarded as M M′, must be inferred from some analogy to other Crystals.

Of the Application of the preceding Tables.

(114.) The *oblique rhombic prism* will be distinguishable from the right rhombic even when the inclination of P on M is very nearly 90°, by the want of correspondig planes on the front and back of the Crystal in the Modifications *a* or *c*, *b*, or *d*, and *f* or *g*, as may be seen by comparing those respectively with Modifications *a*, *b*, and *c* of the right rhombic prism.

The distinction between the secondary forms of this prism and of the rhomboid have been already pointed out in the Tables of Modifications.

The primary planes of this class of prisms are to be determined either by cleavage or from its secondary planes. The varieties of cleavage that occasionally present themselves may be seen by referring to the different minerals whose Crystals assume this form.

(115.) The *doubly oblique prism* will be found the most difficult of all the primary forms to determine from its secondary Crystals. It is distinguishable from all other forms when its Crystals are single, by the absence of symmetrical planes analogous to those of other prisms; but it very frequently occurs in hemitrope or twin Crystals, which must resemble some of the forms of the oblique rhombic prism, and can then be distinguished only by some reentering angle or other character on the surface of the Crystal. The best guide to a knowledge of these forms is an attentive examination of the Crystals of axinite for simple figures, and cleavelandite for hemitrope forms.

(116.) The *rhomboid* will generally be readily distinguished from all other forms by its three or six-sided pyramidal terminations, and by the three, or six, or nine, or twelve-sided prisms which are derived from it. An examination of the Crystals of carbonate of lime and of oligiste iron will afford abundant examples of secondary forms belonging to this figure.

It will be seen by the Tables of Modifications of the rhomboid, that any mineral may present numerous secondary rhomboids as well as the primary, either of which might be assumed as the fundamental form of the whole. But it is usual to regard that particular rhomboid as the primary, which is indicated by the cleavage planes.

(117.) The manner of holding a Crystal for examination requires some attention on the part of the observer, whose first object should be to discover two or more symmetrical planes, and to hold these either vertically or horizontally as they appear to be either lateral or terminal planes corresponding with some of the figures in the tables. The Crystal may then be attached to a piece of wax-taper in a position corresponding to the apparent symmetry of its planes, and be more minutely examined.

(118.) A circumstance which has not yet been alluded to, but which is by no means of uncommon occurrence, a very disproportionate extension of particular planes, will frequently increase the difficulty of *reading* a Crystal. A very remarkable instance of this character prevails in copper pyrites, and has been the occasion of the erroneous opinions entertained until lately, respecting the primary form of that substance.

In all the works on Mineralogy, prior to that of Professor Mohs, its primary form is stated to be a regular tetrahedron. Mohs, however, discovered that the Crystal was an octahedron with a square base. The two following figures represent Crystals containing *equal numbers of similar planes*; fig. 123 having these planes regularly placed on the octahedron, and fig. 124 repre-

Crystallography.

senting the Crystal as it frequently occurs in nature, with some of its planes considerably enlarged. The same letters are placed on the corresponding planes of each, which are in parallel positions on both figures.

When Crystals of this irregular character occur, it is only by cleavage and by using the goniometer that their true forms can be accurately determined.

Having ascertained by examination and comparison with the tables the *class* of primary forms to which any given Crystal belongs, the angles of its primary and secondary planes must be measured in order to determine the species of the mineral.

(119.) When a Crystal, whose primary and secondary forms are known, is to be described by the assistance of the preceding tables, the primary form is first to be set down, and its Modifications denoted by the letters under which they are arranged in the Tables.

But as each Modification, except those which consist of tangent planes, comprehends an unlimited number of separate planes, differing from each other in the angles at which they incline on the primary, it becomes necessary to add to the tabular letter which expresses the Modification, the angles at which the observed planes incline on the adjacent primary ones.

It has been already seen that *Mod. b* of the square prism, represents an indefinite number of planes varying in their respective inclinations on P, M, and M′. Let a given square prism be modified by planes corresponding to b, and let the inclination of one of the planes on P, M, and M′ be denoted by x, y, and z, these letters signifying any number of degrees and minutes.

A Crystal containing the primary planes of the square prism, and a set of planes belonging to b might then be thus described:

$$\text{Square prism } b\begin{cases} b,\mathrm{P} = x \\ b,\mathrm{M} = y \\ b,\mathrm{M}' = z. \end{cases}$$

The character of the plane being thus established, it may afterwards, in order to avoid the repetition of the measurements, be described as $b1$.

Let us now suppose on another Crystal, another set of planes of the same Modification, inclining on P, M, and M′, at the angles x', y', and z', and a third set inclining on P, M, and M′, at the angles x'', y'', and z''; these planes may be described as $b2$ and $b3$:

$$b2\begin{cases} b2,\mathrm{P} = x' \\ b2,\mathrm{M} = y' \\ b2,\mathrm{M}' = z' \end{cases}$$

$$b3\begin{cases} b3,\mathrm{P} = x'' \\ b3,\mathrm{M} = y'' \\ b3,\mathrm{M}' = z''. \end{cases}$$

It will be convenient to call that plane No. 1, which inclines at the most obtuse angle on the primary plane to which it is referred; that No. 2, which is next in its inclination; and so to denote the series in the order of their respective inclinations on the same primary plane.

This method of description may be applied, whether the three planes have occurred on the same or on different Crystals.

The inclination of the modifying plane on two of the primary planes, is generally sufficient, when a solid angle is modified, for determining the law of decrement; but the third inclination serves as a check upon the accuracy of the other two.

If the lateral edge of any prism whose angles are known, be modified by one or more planes, it will be sufficient to give the inclination of each on either of the lateral primary planes, from which the inclination on the other may be readily deduced.

Of the Symbols employed.

This method of description may be extended to all classes of primary forms; and will convey an accurate description of the planes to which it refers.

Crystals may frequently present themselves whose primary forms are unknown to the observer, and whose secondary planes do not enable him to determine them; in which case drawings of the Crystals should be given, accompanied by the measured angles of the several planes. And it may be remarked that the most valuable information a Mineralogist can receive relative to Crystals, is accurate measurements of their angles, accompanied by figures of the measured Crystals.

The laws of decrement are required for drawing these figures with accuracy; but the figures drawn by the late Mr. Phillips merely from the Crystals themselves, prove that a sufficiently precise idea of the forms of Crystals may be conveyed independently of the laws of decrement, to identify any crystallized mineral from the given figures and measurements.

(120.) It has been seen, that the Modifications on the angles of some of the primary forms comprise planes which are produced by different kinds of decrement, some of which are distinguished by the character —, or \, or /, added to the letter denoting the Modification. And it may possibly appear to some of our readers, that different Modifications ought to have been established for these different planes. This would, however, have rendered the Tables less generally applicable to the description of secondary forms, independently of the theory of decrements, than they are at present, which will be obvious on referring to *Mod. a, b, c,* or *d*, of the doubly oblique prism. All that can be known of any individual plane belonging to either of these, independently of calculation, is, that it belongs to such a Modification, and inclines on two of the adjacent primary planes at particular angles; and this furnishes an accurate record of the particular plane.

But if *Mod. a* had been divided into four classes, it could not be known, without previous calculation, to which of those an observed plane ought to be referred; and the measurement of the Crystal would not in such case afford a sufficient description of the secondary form.

It will be convenient while measuring Crystals to recollect that the sum of the angles at which any plane, whose edges are parallel, inclines on the two planes it intersects, is always equal to the mutual inclination of those planes, increased by 180°. Thus if M on T of the doubly oblique prism measure 117°, and M on i measure 110°, i on T will measure 117° + 180° — 110°.

PART II.

Of the Symbols employed to represent the Laws of Decrement by which the Secondary Planes of Crystals may be produced.

(121.) It has been shown that the molecules in the edges of the *defect* of any primary form occasioned by any law of decrement, are respectively proportional to the numbers by which such law may be expressed. These numbers may be denoted by the letters p, q, r; p and q referring to the terminal edges, and r to the lateral edges.

When a terminal edge is modified, the ratio of p to r will express the law of the modifying plane. When a lateral edge is replaced by a plane, its law will be ex-

pressed by $\frac{p}{q}$. When a plane resulting from a simple decrement replaces an angle, and *intersects the terminal plane parallel to a diagonal,* it will be denoted by $\frac{p}{r}$; q being in this case equal to p, and therefore unnecessary to be introduced into the expression of the law; if the modifying plane intersects a *lateral* plane parallel to a diagonal, q and r must be equal, and the law may be denoted by $\frac{p}{q}$, which will also distinguish this from the preceding class of planes.

(122.) In the Tables of Modifications certain letters are placed on the figures of the primary forms, to denote their edges, angles, and planes.

The order of these letters, A E I O, B C D F, G H, is that of the alphabet, arranged from left to right, according to the ordinary method of writing.

The planes which are parallel to those exhibited in the several primary forms, may be denoted by prefixing the symbol of parallelism ‖ to the letters on those planes, as ‖ P, ‖ M, ‖ T.

(123.) In describing a secondary Crystal, whose primary form is known, and upon whose similar edges or angles any number of new planes have been produced, it is sufficient, generally, to express the law of a single plane of each set. For the change of figure which any primary form has undergone would thus be indicated. And in drawing the Crystal corresponding planes would be placed upon all its similar edges or angles.

It sometimes, however, occurs that all the similar edges or angles of Crystals are not similarly modified, and it will therefore be necessary in these cases to indicate the absence of the modifying plane from some edge or angle, where, according to the law of symmetry, it ought to appear.

Distinct kinds of symbols are also required to distinguish simple from intermediary decrements.

The following examples of the forms and application of symbols to denote the Modifications of a doubly oblique prism will include both these classes, and will sufficiently explain the method of using them.

(124.) The Crystal to be described is first supposed to be held *with the plane marked* P, *horizontal, and with that edge or angle nearest to the eye, on which the decrement to be described has taken place.*

Let the Crystal be modified by a plane belonging to the series comprehended under *Mod. a.*

These planes may incline more or less on either of the adjacent primary planes, and may result either from simple or intermediary decrements.

If the modifying plane intersects the terminal plane parallel to its diagonal, and is occasioned by a decrement of one row of molecules, its symbol is $\overset{1}{O}$, and may be read, one over O. If the decrement consist of two rows in breadth, the symbol is $\overset{2}{O}$, and if by three rows in breadth and two in height, it is $\overset{\frac{3}{2}}{O}$; and so of any other decrement in that direction.

If any plane *a* intersects the plane M parallel to its diagonal, and is produced by a decrement by v rows of molecules, v representing *any whole number or fraction,* it is to be denoted by ${}_{v}O$, and be read, v on the left of O.

If it intersects the plane T parallel to its diagonal, it is to be denoted by O_{v}, and be read, v on the right of O.

If the plane has been produced by an intermediary decrement, consisting of two molecules in the direction of the edge H, three in the direction of D, and four in the direction of F, its symbol is (D 3, H 2, F 4,) and may be read, 3 on the edge D, 2 on H, 4 on F. Of the Symbols employed.

If similar Modifications take place at the angle A, *that angle* is imagined to be *nearest to the eye,* and the new planes are to be described in the same manner as those at the angle O.

If two or more planes modify the same solid angle, the symbols representing them are to be placed immediately following each other. Thus, if the three planes at the angle O should occur on the same Crystal, its change of figure would be thus represented ${}_{v}O$, $\overset{v}{O}$, O_{v}.

If three intermediary decrements should occur on the same solid angle, their symbols would also be placed following each other, thus,

(D 3, H 2, F 4,) (D 4, H 3, F 6,) (D 4, H 1, F 3.)

(125.) To denote a decrement on a terminal edge of a doubly oblique prism, the prism is again supposed to be placed or held with that edge nearest to the eye, the plane P continuing horizontal.

If a terminal edge F be replaced by a plane resulting from a decrement by v rows of molecules, it would be denoted by $\overset{v}{F}$, and be read as before, v over F.

If two dissimilar planes occur on the same terminal edge, the symbol is repeated thus $\overset{v}{F}$, $\overset{v'}{F}$, which expresses the coexistence of the two planes on the same edge.

If the lateral edge G or H be modified, the plane M is supposed to be horizontal with the modified edge nearest to the eye, and the decrement is then expressed by the symbol $\overset{v}{G}$ or $\overset{v}{H}$.

All the symbols of simple decrements are thus similar in their form, and distinct from those which represent intermediary decrements.

(126.) The secondary forms of Crystals may be separated into two principal groups:

1. Those which are strictly symmetrical, as *Mod. a, b, c, d, e,* or *f,* of the cube.
2. Those in which the same Modification does not occur on all the similar edges or angles, and which may be subdivided into two classes:
   - *a.* Those in which *each* edge or angle is replaced by only half the number of planes which the law of symmetry requires.
   - *b.* Those in which only the *alternate* edges or angles are modified.

To represent the secondary forms belonging to the first of these groups, it will be sufficient to indicate the character of a single plane belonging to any set of similar planes.

The secondary form of the cube produced by *Mod. b,* fig. 58, or *c,* fig. 59, may be denoted generally by $\overset{v}{A}$. The symbol representing a particular plane of *Mod. c* might be $\overset{\frac{1}{2}}{A}$: and if these symbols be unaccompanied by any other character, they imply that the solid angles are similarly modified.

An intermediary decrement producing any plane of *Mod. d* may be denoted by the general symbol (B_p, B'_q, B''_r).

The planes of *Mod. e* are denoted by $\overset{1}{B}$, and those of *f* by $\overset{v}{B}$.

Crystallography.

It may here be remarked that planes upon the angles of any primary form which in the Tables of Modifications are said to rest upon the primary planes, are produced by decrements, in which the number of molecules in breadth exceeds the number in height; while in those which rest upon the edges, the number in height exceeds the number in breadth. The numbers or fractions expressing the first of these sets will be always greater than unity, as 2, 3, 4, $\frac{3}{2}$, $\frac{4}{3}$, &c.; and those of the latter always less than unity, as $\frac{1}{2}$, $\frac{2}{3}$, $\frac{3}{4}$, &c.; and the planes in this latter case are carried, as it were, over the solid angle.

(127.) Where an angle or edge of the cube is modified by only *half the number* of planes *d* or *f*, which the law of symmetry requires, the Crystal may be denoted by (0), (B_p, B'_q, B''_r), or (B_p, B'_q, B''_r), (0) according as the plane *d* or *d''* is deficient, the cipher 0 signifying the absence of one of these modifying planes; or, where only one of the pair of planes *f* occurs on an edge of the cube, by $\overset{v}{\underset{0}{B}}$, and if the position of the modifying plane be reversed on the alternate edges, by $\overset{v}{\underset{0}{B}}$, $\overset{0}{\underset{v}{B}}$.

(128.) If only the *alternate* angles are modified by the plane *a*, the symbol would be $\overset{1}{A}$, $\overset{0}{A'}$.

If by the planes *b* or *c*, the symbols might be $\overset{v}{A}$, $\overset{0}{A}$, or A. A' according to the positions of the modified and unmodified angles in the figure 63 whose symbol is $\overset{0}{A}$ $\overset{1}{A'}$.

When *Mod. d* occurs on the alternate angles its symbol might be A (B_p, B'_q, B''_r), A' (0) or A (0), A' (B_p, B'_q, B''_r). But it will be convenient in many cases of defective Modifications to represent the Crystals by figures, in order to avoid the complicated character which the symbols might assume.

(129.) It will be convenient when the secondary forms of Crystals are described by means of these symbols, to observe some certain order in their arrangement into what may be termed the theoretical image of the Crystal; although the particular order in which they are placed is a matter of indifference.

The primary planes may be placed first, and then the different Modifications in the order in which they are given in the Tables, and denoted by the same letters.

Thus if a right rhombic prism should be modified by planes belonging to *a*, *c*, *e*, *h*, and *g*, and also retain portions of the primary planes, the representative symbol might be this,

$$P,\ M,\ \underset{a}{\overset{3}{A}},\ \underset{c}{\overset{2}{E}},\ \underset{e}{\overset{1}{B}},\ \underset{g}{\overset{2}{H}},\ \underset{h}{\overset{1}{G}}.$$

Here the laws of decrement producing the secondary planes are represented by the upper series of symbols, and the lower series consists of the letters on the corresponding modifying planes in the figure of the Crystal.

The relations of these symbols to the several Modifications will be seen in the following Table.

(130.) It may not be useless to remark, that the indices employed in this Treatise to represent planes produced by *intermediary* decrements, are always whole numbers; whereas the symbols used by Haüy to represent similar planes, frequently contain fractional indices.

There is not, however, any real difference in the character of the plane so denoted, by the two methods of representing it.

A particular plane modifying the angle O of the doubly oblique prism would be expressed by Haüy as ($D2\overset{2}{O}F3$), and would be understood to imply that the compound molecules abstracted in the production of the new plane, consisted of smaller compound ones, each being three molecules in height, and two in breadth, repeated twice on the edge D, and three times on the edge E.

It will hence be readily perceived, that if in Haüy's symbol we substitute for the *letter* denoting the *angle* on which the decrement is conceived to take place, *that* which denotes the *edge* upon which that angle may be said to rest, and place the denominator of his fraction after it as its proper index; and if we muliply at the same time his other indices by the numerator of his fraction, the new symbol will be similar in character to those which are contained in this Treatise.

This method of converting the form of the one symbol into that of the other, may be considered general, and by reversing the process, the symbols given in these pages may be converted into the form of those which he has used.

Table of Symbols corresponding to the several Modifications of the Primary Forms.

Table of Symbols corresponding to the several Modifications of the Primary Forms.

(131.) It is evident from what has preceded, that $\overset{1}{A}$ and A_1 must represent the same plane, because a decrement by one row produces a plane that intersects the three adjacent primary planes parallel to their diagonals. But it is convenient to express this decrement by the symbol $\overset{1}{A}$. And hence in the symbol $_vA$ or A_v, v must always be greater or less than 1.

Calculation of the Laws of Decrement.

(132.) The symbols given in the preceding Table express in general terms the Laws of Decrement which produce the several Modifications before described.

To determine the law of any particular plane belonging to any Modification, the particular values of p, q, and r, or of p and r, in relation to such plane, must be found.

It has been shown (42.) that the edges of the *defect* of any primary form are, when the decrement producing it consists of one row of molecules, proportional to the corresponding primary edges, being in all other cases respectively proportional parts of those edges. And the problem of determining the particular values of p, q, and r, is in reality that of finding the proportions of the several primary edges which are cut off by the modifying plane, and which constitute the edges of the defect.

(133.) When the primary edges are unequal, the terminal ones, if equal, may be expressed by m, and the lateral edges by n. When the terminal edges are unequal, as in the doubly oblique prism, one of them may be denoted by m, and the other by o, and the lateral edges by n. When a decrement by one row of molecules produces a new plane, it is evident that $\frac{p}{r}$ will be equal to $\frac{m}{n}$.

When a plane is produced by any other law, the ratio of the edges of the defect will assume the form of $\frac{p\,m}{r\,n}$, and the Law of Decrement $\frac{p}{r}$, or v, is obtained if the ratio of the edges of the defect be divided by the ratio of the corresponding primary edges.

But the Law of Decrement may in particular cases be more conveniently determined from the ratio of an edge to some other line which would be proportionally intercepted by the modifying plane, and which may, when necessary, be denoted by l.

31.) The following is a general method of discovering the Law of Decrement, by which any new plane has been produced upon any primary form.

To ascertain the ratio of $i\,b$ to $i\,c$, fig. 125, being the edges of the *defect* produced by a decrement on an edge of any parallelopiped, the inclination of the primary planes to each other being known, and also the inclination of the modifying plane $a\,b\,c\,f$ to the primary planes P and T, the angles of the plane triangle $i\,b\,c$ are required.

These may be obtained by means of a spherical triangle, whose angle A is the supplement of the inclination of P on the plane $a\,b\,c\,f$, B the inclination of P on T, and C the supplement of the inclination of T on $a\,b\,c\,f$.

From this spherical triangle the side a containing the required angle $i\,b\,c$ may be deduced from the known formula,

$$\sin \tfrac{1}{2} a = \mathrm{R}\left(\frac{-\cos \frac{1}{2}(A+B+C) \, . \, \cos \frac{1}{2}(B+C-A)}{\sin B \, . \, \sin C}\right)^{\frac{1}{2}}$$

and by applying the same formula to a second spherical triangle, whose angle

C is similar to that of the preceding,

B is the inclination of M on T,

A the supplement of M on $a\,b\,c\,f$.

derived from actual measurement, or deduced from its

Crystallography.

known inclination on P, and of P on M, the side a, which contains the other required angle $i\ c\ b$, may be obtained.

Having thus determined the two plane angles, $i\ b\ c$, $i\ c\ b$, the ratio of $i\ b$ to $i\ c$ is known from the relation of the sines of the angles of triangles to the sides subtending those angles, thus,

$$i\ b : i\ c :: \sin i\ c\ b : \sin i\ b\ c.$$

If the new plane has resulted from a decrement on the edge $h\ i$, by one row of molecules, the lines $i\ b$, $i\ c$, must be to each other as m to n, and then

$$\sin i\ c\ b : \sin i\ b\ c :: m : n.$$

But if the new plane has resulted from a decrement by unequal numbers in breadth and in height, the ratio of $i\ b$ to $i\ c$ will be as $p\ m$ to $r\ n$, p representing the number of molecules abstracted in the direction $i\ k$, and r the number in the direction $i\ d$; and dividing this ratio by $\frac{m}{n}$, a Law of Decrement is given of p rows in breadth, or in the direction of $i\ k$, and q in height, or in the direction of the edge $i\ d$.

(135.) The ratios of the three edges, $i\ b$, $i\ c$, $i\ a$, fig. 126, intercepted by a decrement on one of the angles of a parallelopiped, may be thus determined.

The inclination of the primary planes to each other being known, the three plane angles at i may be deduced by means of a spherical triangle; and having measured the inclination of the plane $a\ b\ c$ on P, M, and T, the plane angles at a, b, and c may be discovered by means of two spherical triangles, whose angles are those at which the primary planes incline to each other, and the supplements of those at which the secondary plane inclines on the adjacent primary planes.

The plane angles at a, b, and c, being found, the Law of Decrement may be determined from the ratios of $i\ b : i\ c$ and $i\ b : i\ a$.

Let	$i\ k : i\ d :: m : n,$
and	$i\ k : i\ h :: m : o,$
and let	$i\ b : i\ c :: p\ m : r\ n,$
	$i\ b : i\ a :: p\ m : q\ o.$

After dividing $\frac{p\ m}{r\ n}$ by $\frac{m}{n}$, and $\frac{p\ m}{q\ o}$ by $\frac{m}{o}$,

we find
$$i\ b = p,$$
$$i\ a = q,$$
$$i\ c = r,$$

implying a decrement by p molecules in the direction of $i\ k$, q in that of $i\ h$, and r in that of $i\ d$.

If fig. 126 be a doubly oblique prism, and the edges $i\ h$, $i\ k$, $i\ d$, be respectively denoted by D, F, H, the symbol of the plane, $a\ b\ c$, would be ($F_p\ D_q\ H_r$).

By this general method, when the inclinations of the primary planes to each other are known, and also that of the secondary plane on one or more of the primary, the Law of Decrement may be found by which any secondary plane has been produced on any primary form.

But as it will appear in the sequel, the methods of determining this law become much more simple in reference to several of the primary forms.

It may not be useless again to observe, that when a Law of Decrement producing any plane is to be determined, its *general symbol* is first to be found in the preceding Tables, and then the *particular values* of its *indices* are to be determined.

In simple decrements, these values may be deduced from some simple ratio, as that of radius to tangent, or of sin a to sin b, and the following may be regarded as the general process for determining the law of an intermediary decrement.

Calculation of the Laws of Decrement.

1. To measure the inclination of the secondary planes on two of the adjacent primary planes.
2. To determine the two plane angles at the termination of the greater edge of the *defect* of the primary form occasioned by the secondary plane.
3. From a knowledge of these plane angles, and of the plane angles of the primary planes, to deduce the ratios of the edges of the *defect*.
4. To divide these ratios by the ratios of the corresponding edges of the primary form, and thus to deduce the Law of Decrement.

(136.) From what has preceded it will be readily perceived that the ratios of the primary edges of Crystals may be determined, by assuming some observed secondary plane replacing an edge of those forms whose terminal edges are equal, or replacing an angle of those whose terminal edges are unequal, to have been produced by some given Law of Decrement. If by *one* row of molecules the ratio of the primary edges corresponds to that of the *edges* of the *defect* occasioned by such plane. And if any other law be assumed, the ratios of the primary edges may evidently be determined, from the division of the ratios of the edges of the defect by the assumed Law of Decrement.

(137.) In the methods about to be given of determining the Laws of Decrement in relation to each of the primary forms, a *single* reference only is given in each case to the figures contained in the Tables of Modifications, and to one or two other explanatory ones. This has been done to avoid the confusion of perpetual references to different figures. And it is to be understood that whenever the *inclination* of *two planes* is given, as P,a, P,b, &c. *these letters* refer to the *Tables of Modifications;* and whenever any *lines or plane angles* are referred to as line $a\ b$, or angle $a\ b\ c$, *these will be found on the explanatory figures.*

(138.) The inclination of the primary planes, the ratios of the primary edges, &c., are termed the *crystallographical elements* of the primary form.

It will be found particularly convenient in examining and describing Crystals, to determine these elements in the first instance for each particular substance, so as to have them ready for computing the Laws of Decrement of the modifying planes.

The formulæ given for this purpose are generally derived from spherical trigonometry, and are in most instances so easily deduced as to render demonstration unnecessary. And as the division by $\frac{m}{n}$ or $\frac{l}{n}$ is already effected in these, they immediately give the value to be substituted for $\frac{p}{r}$ or its equivalent v in the general symbol.

The reader will thus have before him, Tables of all the groups of forms which can result from regular Crystallization; Tables of the *Laws of Decrement* expressed in *general terms*, by which the modifying planes of these groups might be respectively produced; and the means of determining the *particular* law from which any *individual plane* of *either* of these *groups* might result.

Some other relations among primary and secondary forms will also be pointed out.

THE CUBE.

Fig. 56 to 64, and 127.

Crystallographical Elements.

(139.) Inclination of any two adjacent planes = 90°.
Plane angles = 90°.
Edges equal.
Inclination of an edge to an oblique axis = 54° 44′ 8″.

(140.) Ratio of half a diagonal to an edge.

$$h\,f : f\,c :: 1 : \sqrt{2}.$$

(141.) Ratio of an edge to an oblique axis,

$$f\,c : c\,g :: 1 : \sqrt{3}.$$

Simple Decrements on the Angles producing planes b. and c.

General symbol $\dot{A}$

(142.) $$v = \frac{R\sqrt{2}}{\tan(180° - P,b)}.$$

(143.) $$= \frac{R\sqrt{2}}{\tan(180° - P,c)},$$

(144.) The expression $\tan(180° - P,b)$ is used instead of $-\tan P,b$ to point out more clearly the derivation of the given angle; an observation which will apply to future similar expressions of this and other trigonometrical lines.

(145.) It is evident that $h\,f$, half the diagonal $g\,f$, is intercepted at the point h by the edge $a\,b$ of a secondary plane resulting from a decrement by one row of molecules, and would be intercepted, proportionally to the edges, by any other law. It is therefore used instead of an edge for expressing the Laws of Decrement producing the planes b and c.

Decrements on the Edges.

General symbol $\dot{B}$.

(146.) $$c = \frac{R}{\tan(180° - P,f)}.$$

Intermediary Decrements.

The general symbol representing a plane of *Mod. d* is $(B_p\, B'_r\, B''_r)$.

(147.) $$\cos k\,i\,f = \frac{R.\cos(180° - P',d)}{\sin(180° - P,d)}.$$

(148.) $$\cos f\,i\,d = \frac{R.\cos(180° - P,d)}{\sin(180° - P',d)}.$$

Two plane angles of the defect being thus found, we have,

$$i\,f : f\,k :: R : \tan k\,i\,f :: p : q,$$
$$i\,f : f\,d :: R : \tan f\,i\,d :: p : r.$$

(149.) When any of the modifying planes, b, c, d, or f, occur upon the tetrahedron, octahedron, or rhombic dodecahedron, their respective inclinations to the planes of the cube must be inferred from the angles at which some of them incline to each other.

The positions of such planes upon the tetrahedron, the octahedron, and rhombic dodecahedron may be readily found from their relation to the Modifications which produce those forms.

Thus, $$P,b = 305° 15' 52'' - b,a$$
$$= 270° - b,e''$$
$$P,e'' = a,e'' - 54° 44' 8'$$
$$= 270° - e',e''$$
$$P,f = 225° - \tfrac{1}{2} f,f'.$$

THE SQUARE PRISM.

Fig. 65 to 70, and 128.

Crystallographical Elements

(150.) Inclination of any two adjacent planes = 90°.
Plane angles = 90°.
Terminal edges equal.
Lateral edges equal.

(151.) Ratio of terminal to lateral edge,

$$d\,a : a\,f :: m : n.$$

(152.) Ratio of terminal edge to half diagonal of terminal plane,

$$d\,a : a\,b :: \sqrt{2} : 1.$$

(153.) Ratio of half diagonal of terminal plane to lateral edge,

$$a\,b : a\,f :: \frac{m}{\sqrt{2}} : n.$$

(154.) Ratio of terminal edge to perpendicular upon diagonal $e\,f$,

$$d\,a : a\,c :: m : \frac{m\,n}{(m^2 + n^2)^{\frac{1}{2}}}$$

(155.) $$\tan a\,e\,f = \frac{R\,n}{m}$$

$$a\,e : a\,f :: m : n :: R : \tan a\,e\,f.$$

(156.) The ratio, $m : n$ of the primary edges can be determined only from the inclination of the primary to some secondary plane, assumed to be produced by a given Law of Decrement.

If a or c be assumed to have resulted from a decrement by one row of molecules, the ratio of the edges of the defect occasioned by either of these planes must, as already explained, correspond to that of the primary edges. If some other Law of Decrement be assumed, the ratio of the edges of the defect must then be divided by that law to obtain the ratio of the primary edges.

After the explanations already afforded of the methods employed for discovering the Laws of Decrement, it does not appear necessary in future to do more than to give the *general* symbol of each of the Modifications, and the formulæ by which the *particular* values of p, q, and r, in each symbol, are to be deduced.

Simple Decrements on the Angles.

General symbols $\dot{A}$, $A_{\prime\prime}$.

(157.) $A_{\prime\prime}$ $$v = \frac{n\,R\sqrt{2}}{m.\tan(180° - P,a)}.$$

This formula expresses the ratio of the whole lateral edge to its defect, and also the *numerical* ratio of half a terminal diagonal to the same defect.

(158.) $\dot{A}$, $$v = \frac{(m^2 + n^2)^{\frac{1}{2}} R}{n.\tan(180° - M,b)}.$$

Decrements on the Edges.

General symbols $\dot{B}$, $\dot{G}$.

(159.) $\ddot{B}$, $$v = \frac{n\,R}{m.\tan(180° - P,c)}.$$

(160.) $\overset{v}{\mathrm{G}}$, $\quad r = \dfrac{\mathrm{R}}{\tan(180^\circ - \mathrm{M},c)}$.

If $v = 1$ in (157.) or (159.) the ratio of the primary edges may be immediately obtained.

Intermediary Decrements.

(161.) $\quad \cos i\,g\,a = \dfrac{\mathrm{R}\,.\,\cos(180^\circ - \mathrm{M},b)}{\sin(180^\circ - \mathrm{P},b)}$.

(162.) $\quad \cos a\,g\,k = \dfrac{\mathrm{R}\,.\,\cos(180^\circ - \mathrm{P},b)}{\sin(180^\circ - \mathrm{M},b)}$.

Whence $\quad a\,g : a\,i :: \mathrm{R} : \tan i\,g\,a :: p : q,$

$\qquad\quad a\,g : g\,k :: \mathrm{R} : \tan a\,g\,k :: p : r.$

In the examination of Crystals it is frequently necessary to ascertain the inclination of particular planes which cannot be measured, by means of known angles; or to determine the inclinations of planes in particular directions from their known angles in other directions. For which purposes the following formulæ will be found useful:

$$\mathrm{P},a = 180^\circ - \tfrac{1}{2}\,a',a''.$$

(163.) $\quad \sin\tfrac{1}{2}\,a',a'' = \sqrt{2}\,.\,\cos\tfrac{1}{2}\,a,a'$
$\qquad\qquad = \cos\tfrac{1}{2}\,a,a''.$

The same relations subsist between c,c', c,c'', and c,c'''.

The plane angle at the base of an octahedron derived from *Mod. a* or *c* being denoted by r may be thus found:

(164.) $\quad \cos r = \dfrac{\mathrm{R}\,.\,\cot\frac{1}{2}\,c',c'''}{\tan\frac{1}{2}\,c,c'}$.

(165.) From the preceding equations,

$$\frac{\mathrm{R}\,\sqrt{2}}{\tan(180^\circ - \mathrm{P},a)} = \frac{\mathrm{R}}{\tan(180^\circ - \mathrm{P},c)};$$

(166.) Whence

$$\tan(180^\circ - \mathrm{P},a) = \sqrt{2}\,.\,\tan(180^\circ - \mathrm{P},c).$$

This relation obviously subsists between the planes whose indices are $\overset{v}{\mathrm{A}}$ and $\overset{v}{\mathrm{B}}$, whenever v is the same in both.

(167.) And if v be equal in equations 2 and 5, we have

$$\frac{n\,\mathrm{R}\,\sqrt{2}}{m\,.\,\tan(180^\circ - \mathrm{P},a)} = \frac{\mathrm{R}\,(m^2 + n^2)^{\frac{1}{2}}}{n\,.\,\tan(180^\circ - \mathrm{M},b)}.$$

(168.) Whence $\tan\mathrm{P},a = \tan\mathrm{M},b\,\dfrac{n^2\sqrt{2}}{m\,(m^2 + n^2)^{\frac{1}{2}}}$.

(169.) And, $\quad \tan\mathrm{P},c = \tan\mathrm{M},b\,\dfrac{n^2}{m\,(m^2 + n^2)^{\frac{1}{2}}}$.

(170.) If, in equation 2, $v = 1$, and in 5, $v = \dfrac{p}{r}$,

then $\quad \dfrac{n\,\mathrm{R}\,\sqrt{2}}{m.\tan(180^\circ - \mathrm{P},a)} = \dfrac{r\,\mathrm{R}\,(m^2 + n^2)^{\frac{1}{2}}}{p\,n\,.\,\tan(180^\circ - \mathrm{M},b)}$.

(171.) Whence $\tan\mathrm{P},a = \tan\mathrm{M},b\,\dfrac{p\,n^2\sqrt{2}}{r\,m\,(m^2 + n^2)^{\frac{1}{2}}}$.

It may be remarked that a regular eight-sided pyramid the planes of which are isosceles triangles, cannot be produced on the square prism by any regular Law of Decrement.

THE RIGHT RHOMBIC PRISM.

Fig. 71 to 82, and 129.

Crystallographical Elements.

(172.) Inclination of terminal to lateral planes $= 90^\circ$.
Inclination of lateral planes differs in different minerals. The greater angle is denoted by M,M′.
Terminal plane angles correspond to angles of prism.
Lateral plane angles $= 90^\circ$.
Terminal edges equal.
Lateral edges equal.

(173.) Ratio of terminal to lateral edge,

$$e\,f : e\,m :: m : n.$$

(174.) Ratio of terminal edge to half lesser diagonal of terminal plane,

$$e\,f : f\,n :: \mathrm{R} : \cos\tfrac{1}{2}\,\mathrm{M},\mathrm{M}'$$
$$:: m : \frac{m\,.\,\cos\frac{1}{2}\,\mathrm{M},\mathrm{M}'}{\mathrm{R}}.$$

(175.) Ratio of terminal edge to half greater diagonal of terminal plane,

$$e\,f : e\,n :: \mathrm{R} : \sin\tfrac{1}{2}\,\mathrm{M},\mathrm{M}'$$
$$:: m : \frac{m\,.\,\sin\frac{1}{2}\,\mathrm{M},\mathrm{M}'}{\mathrm{R}}.$$

(176.) Ratio of half lesser diagonal of terminal plane to lateral edge,

$$n\,f : f\,l :: \frac{m\,.\,\cos\frac{1}{2}\,\mathrm{M},\mathrm{M}'}{\mathrm{R}} : n.$$

(177.) Ratio of half greater diagonal of terminal plane to lateral edge,

$$n\,e : e\,m :: \frac{m\,.\,\sin\frac{1}{2}\,\mathrm{M},\mathrm{M}'}{\mathrm{R}} : n.$$

(178.) Ratio of $f\,g$ (perpendicular on $i\,k$) to lateral edge,

$$f\,g : f\,l :: \frac{m\,.\,\cos(\mathrm{M},\mathrm{M}' - 90^\circ)}{\mathrm{R}} : n.$$

(179.) The angle $f\,k\,l$ may be found from the equation

$$\tan f\,k\,l = \frac{n\,\mathrm{R}}{m}.$$

Simple Decrements on the Terminal Angles.

(180.) $\overset{v}{\mathrm{A}}$, $\quad v = \dfrac{n\,\mathrm{R}^2}{m\,.\cos\frac{1}{2}\,\mathrm{M},\mathrm{M}'\,.\,\tan(180^\circ - \mathrm{P},a)}$.

(181.) $\overset{v}{\mathrm{E}}$, $\quad v = \dfrac{n\,\mathrm{R}^2}{m\,.\sin\frac{1}{2}\,\mathrm{M},\mathrm{M}'\,.\,\tan(180^\circ - \mathrm{P},c)}$.

Decrements on the Edges.

(182.) $\overset{v}{\mathrm{B}}$, $\quad v = \dfrac{n\,\mathrm{R}^2}{m\,.\cos(\mathrm{M},\mathrm{M}' - 90^\circ)\,.\,\tan(180^\circ - \mathrm{P},e)}$.

(183.) $\overset{v}{\mathrm{H}}$, $\quad v = \dfrac{\sin(180^\circ - \mathrm{M},g)}{\sin(\mathrm{M},g - \mathrm{M},\mathrm{M}')}$.

(184.) $\overset{v}{\mathrm{G}}$, $\quad v = \dfrac{\sin(180^\circ - \mathrm{M},i)}{\sin(\mathrm{M},i + \mathrm{M},\mathrm{M}' - 180^\circ)}$.

(185.) If, in the general formula for $\overset{v}{\mathrm{A}}$, we make $v = 1$,

$$\frac{m}{n} = \frac{\mathrm{R}^2}{\sin\frac{1}{2}\,\mathrm{M},\mathrm{M}'\,.\,\tan(180^\circ - \mathrm{P},a)}$$

which gives the ratio of the primary edges; or it may

be derived in a similar manner from the formulæ for $\overset{v}{E}$ or $\overset{v}{B}$ by making $v = 1$, and then dividing both sides of the equation by n and multiplying by m.

Simple Decrements corresponding to the Symbols A_v *and* E_v, *and Intermediary Decrements.*

(186.) $\cos b\,a\,f = \dfrac{R\,.\,\cos(180^\circ - M,b)}{\sin(180^\circ - P,b)}$.

(187.) $\cos f\,a\,c = \dfrac{R\,.\,\cos(180^\circ - P,b)}{\sin(180^\circ - M,b)}$.

(188.) $fa : fb :: \sin(180^\circ - M,M' - b\,a\,f) : \sin b\,a\,f$,

$$:: n\,R : \frac{n\,R\,.\,\sin b\,a\,f}{\sin(180^\circ - M,M' - b\,a\,f)},$$

$$:: p : q :$$

(189.) $fa : fc :: R : \tan f\,a\,c$

(190.) In relation to *Mod. d*,

$$\cos u\,v\,e = \frac{R\,.\,\cos M,d}{\sin P,d}$$

(191.) $\cos e\,v\,w = \dfrac{R\,.\,\cos P,d}{\sin M,d}$,

Whence

(192.) $ve : eu :: \sin(M,M' - u\,v\,e) : \sin u\,v\,e$,

$$:: n\,R : \frac{n\,R\,.\,\sin u\,v\,e}{\sin(M,M' - u\,v\,e)},$$

$$:: p : q :$$

(193.) $ev : cw :: m\,R : n\,.\,\tan e\,v\,w$,

$$:: p : r.$$

If the angle $f\,a\,c$ or $e\,v\,w$, deduced from either of the preceding formulæ, be equal to the angle $f\,e\,l$, or $e\,f\,m$, the plane to which it relates has for its symbol A or E, and the edges of the defect corresponding to $e\,f$, $f\,l$, or $e\,f$, $e\,m$, must be in the ratio of m to n, and hence the ratio of the third edge to either of these determines the Law of Decrement.

(194.) The following formula may be useful in examining Crystals:

$$\sin \tfrac{1}{2} M,M' = R\,\frac{\cos \frac{1}{2}\,e',e''}{\sin \frac{1}{2}\,e',e'''}.$$

And it may be observed that the planes of *Mod. i* can never meet at an angle equal to M,M′, unless M,M′ = 120°.

THE OBLIQUE RHOMBIC PRISM.

Fig. 83 to 94, and 130.

Crystallographical Elements.

(195.) Inclination of terminal to lateral planes varies in different minerals.

Inclination of lateral planes varies in different minerals, and M,M′ may be either acute or obtuse.

(196.) Terminal and lateral plane angles may be thus ound:

$$\cos \tfrac{1}{2} f\,a\,d = \frac{R\,.\,\cos \frac{1}{2} M,M'}{\sin P,M}.$$

(197.) $\cos f\,a\,e = \dfrac{\cot P,M\,.\,\cot \frac{1}{2} M,M'}{R}$.

Terminal edges equal.

Lateral edges equal.

(198.) Ratio of terminal to lateral edge,

$$fa : fm :: m : n.$$

(199.) Inclination of oblique diagonal $g\,a$ to oblique edge $a\,e$ may be thus found:

$$\cos g\,a\,e = \frac{R\,.\,\cos P,M}{\sin \frac{1}{2} M,M'}.$$

(200.) Ratio of terminal edge to half oblique diagonal,

$$af : ah :: R : \cos \tfrac{1}{2} f\,a\,d.$$

$$:: m : \frac{m\,.\,\cos \frac{1}{2} f\,a\,d}{R}$$

$$:: \sin P,M : \cos \tfrac{1}{2} M,M'$$

$$:: m : \frac{m\,.\,\cos \frac{1}{2} M,M'}{\sin P,M}.$$

(201.) Ratio of terminal edge to half horizontal diagonal,

$$af : fh :: R : \sin \tfrac{1}{2} f\,a\,d$$

$$:: m : \frac{m\,.\,\sin \frac{1}{2} f\,a\,d}{R}$$

$$:: m : \frac{m\{(\sin P,M)^2 - (\cos \frac{1}{2} M,M')^2\}^{\frac{1}{2}}}{\sin P,M}.$$

(202.) For $(\sin \tfrac{1}{2} f\,a\,d)^2 = R^2 - (\cos \tfrac{1}{2} f\,a\,d)^2$

$$= R^2 - \frac{R^2 (\cos \frac{1}{2} M,M')^2}{(\sin P,M)^2},$$

$$= \frac{R^2\{(\sin P,M)^2 - (\cos \frac{1}{2} M,M')^2\}}{(\sin P,M)^2};$$

(203.) $\therefore \dfrac{\sin \frac{1}{2} f\,a\,d}{R} = \dfrac{\{(\sin P,M)^2 - (\cos \frac{1}{2} M,M')\}^{\frac{1}{2}}}{\sin P,M}$.

(204.) Ratio of half oblique diagonal to lateral edge,

$$ah : ae :: \frac{m\,.\,\cos \frac{1}{2} f\,a\,d}{R} : n,$$

$$:: \frac{m\,.\,\cos \frac{1}{2} M,M'}{\sin P,M} : n.$$

(205.) Ratio of half horizontal diagonal to lateral edge,

$$fh : fm\,(= ae) :: \frac{m\,.\,\sin \frac{1}{2} f\,a\,d}{R} : n.$$

(206.) $:: \dfrac{m\{(\sin P,M)^2 - (\cos \frac{1}{2} M,M')^2\}^{\frac{1}{2}}}{\sin P,M} : n.$

(207.) Ratio of half horizontal diagonal to fr perpendicular to $r\,m$,

$$fh : fm :: m\,.\,\sin \tfrac{1}{2} f\,a\,d : n\,R,$$

$$fm : fr :: R : \cos(g\,a\,e - 90^\circ),$$

$$:: n\,R : n\,.\,\cos(g\,a\,e - 90^\circ),$$

(208.) $fh : fr :: m\,.\,\sin \tfrac{1}{2} f\,a\,d : n\,.\,\cos(g\,a\,e - 90^\circ)$.

(209.) The angles $f\,a\,m$ and $f\,m\,a$ may be thus found:

Let S = their sum $= f\,a\,e$,

D = their difference,

$s = m + n$, the sum of the sides containing $f\,a\,e$ or $m\,f\,a$,

$d = m - n$, their difference,

$$\tan \tfrac{1}{2} D = \frac{d\,.\,\tan \frac{1}{2} S}{s},$$

$\frac{1}{2} S + \frac{1}{2} D$ = greater angle,

$\frac{1}{2} S - \frac{1}{2} D$ = lesser angle,

and the greater angle will be subtended by the greater edge of the prism.

(210.) Ratio of ab, perpendicular to gd, to ac, perpendicular to me,

$$ab : ad :: \cos(fad - 90^\circ) : \mathrm{R},$$
$$:: \frac{m.\cos(fad-90^\circ)}{\mathrm{R}} : m,$$
$$ad : ae :: \quad m \quad : n,$$

(211.) $ae : ac :: \quad \mathrm{R} \quad : \cos(fae - 90^\circ)$,

(212.) $\therefore ab : ac :: m.\cos(fad-90^\circ) : n.\cos(fac-90^\circ)$.

When fad is an acute angle,

(213.) $ad : ab' :: \mathrm{R} : \cos(90^\circ - fad)$
$$:: \mathrm{R} : \sin fad.$$

(214.) Hence $ab' : ac :: m.\sin fad : n.\cos(fac-90^\circ)$.

Simple Decrements on the Terminal Angles.

(215.) $\overset{n}{\mathrm{O}}, \quad v = \dfrac{n\,\mathrm{R}.\sin(\mathrm{P},a - hac)}{m.\cos\frac{1}{2}fad.\sin(180^\circ - \mathrm{P},a)}$.

(216.) $\overset{n}{\mathrm{A}}, \quad v = \dfrac{n\,\mathrm{R}.\sin(\mathrm{P},c' + hac - 180^\circ)}{m.\cos\frac{1}{2}fad.\sin(180^\circ - \mathrm{P},c')}$.

(217.) $\overset{n}{\mathrm{E}}, \quad v = \dfrac{n\,\mathrm{R}.\cos(gae - 90^\circ)}{m.\sin\frac{1}{2}fad.\tan(180^\circ - \mathrm{P},e)}$.

Decrements on the Edges.

When $\mathrm{M,M'} > 90^\circ$,

(218.) $\overset{n}{\mathrm{D}}, v = \dfrac{n.\cos(fae-90^\circ).\sin(\mathrm{P},f - \mathrm{P,M})}{m.\cos(fad-90^\circ).\sin(180^\circ - \mathrm{P},f)}$.

(219.) $\overset{n}{\mathrm{B}}, v = \dfrac{n.\cos(fae-90^\circ).\sin(\mathrm{P},g + \mathrm{P,M} - 180^\circ)}{m.\cos(fad-90^\circ).\sin(180^\circ - \mathrm{P},g)}$.

When $\mathrm{M,M'} < 90^\circ$,

(220.) $\overset{n}{\mathrm{D}}, v = \dfrac{n.\cos(fae-90^\circ).\sin(\mathrm{P},f - \mathrm{P,M})}{m.\sin fad.\sin(180^\circ - \mathrm{P},f)}$.

(221.) $\overset{n}{\mathrm{B}}, v = \dfrac{n.\cos(fae-90^\circ).\sin(\mathrm{P},g + \mathrm{P,M} - 180^\circ)}{m.\sin fad.\sin(180^\circ - \mathrm{P},g)}$.

If $\mathrm{M,M'} >$ or $< 90^\circ$,

(222.) $\overset{n}{\mathrm{H}}, \quad v = \dfrac{\sin(\mathrm{M}',i' - \mathrm{M,M'})}{\sin(180^\circ - \mathrm{M}',i')}$.

(223.) $\overset{n}{\mathrm{G}}, \quad v = \dfrac{\sin(\mathrm{M},l + \mathrm{M,M'} - 180^\circ)}{\sin(180^\circ - \mathrm{M},l)}$.

It is evident that if $v = 1$ in any of the preceding formulæ except the two last, the ratio of m to n may be immediately obtained.

Simple Decrements upon the Lateral Angles, and Intermediary Decrements.

(224.) Let the defect occasioned by a given plane be regarded as a spherical triangle, the angles of which are

$$\mathrm{A} = 180^\circ - \mathrm{P},b$$
$$\mathrm{B} = \mathrm{P,M}$$
$$\mathrm{C} = 180^\circ - \mathrm{M},b.$$

The side c may be obtained from the formula

$$\sin\tfrac{1}{2}c = \mathrm{R}\left(\frac{-\cos\frac{1}{2}(\mathrm{A+B+C}).\cos\frac{1}{2}(\mathrm{A+B-C})}{\sin \mathrm{A}.\sin \mathrm{B}}\right)^{\frac{1}{2}},$$

and the side a from another corresponding to it.

If the side a be equal to the angle afe its intersection with M will be parallel to a diagonal fe of that plane, and its symbol will then be $\mathrm{O}_{,}$, and the ratio of the edges of the defect corresponding to the *terminal* edges of the prism will give the Law of Decrement. But if b do not intersect M parallel to a diagonal, the symbol of the measured plane is $(\mathrm{D}_{,}\mathrm{D}'_{,}\mathrm{H}_{,})$ and the ratios of the three edges of the defect must be found by the general method already explained.

Similar observations may be applied to the planes d whose symbol is either A, or $(\mathrm{B}_{,}\mathrm{B}'_{,}\mathrm{H}'_{,})$, and to those planes e whose symbol is ${}_{,}\mathrm{E}$, or $\mathrm{E}_{,,}$ or $(\mathrm{B}'_{,}\mathrm{D}_{,}\mathrm{G}_{,})$.

A repetition of the formulæ for these cases is unnecessary after the explanation already given, but it may be convenient to have the angles of the spherical triangles for determining the indices of those planes.

(225.) For d, $\quad \mathrm{A} = 180^\circ - \mathrm{P},d$
$$\mathrm{B} = 180^\circ - \mathrm{P,M}$$
$$\mathrm{C} = 180^\circ - \|\mathrm{M},d;$$

for e, where its symbol is ${}_{,}\mathrm{E}$,

(226.) $\quad \mathrm{A} = 180^\circ - \mathrm{P},e$
$$\mathrm{B} = 180^\circ - \mathrm{P,M}$$
$$\mathrm{C} = 180^\circ - \|\mathrm{M}',e;$$

where its symbol is $\mathrm{E}_{,,}$

(227.) $\quad \mathrm{A} = 180^\circ - \mathrm{P},e$
$$\mathrm{B} = \mathrm{P,M}$$
$$\mathrm{C} = 180^\circ - \mathrm{M},e:$$

and *either* of these two latter sets of angles may be used where the symbol is $(\mathrm{B}'_{,}\mathrm{D}_{,}\mathrm{G}_{,})$.

THE DOUBLY OBLIQUE PRISM.

Fig. 95 to 105, and fig. 131.

Crystallographical Elements.

(228.) Inclination of terminal to lateral planes is different in different minerals, and P,M differs also from P,T.

Inclination of lateral planes M,T varies in different minerals.

In the figure, and in the following remarks, P,M, P,T, M,T are all supposed greater than 90°, and the edges D, F, and H are consequently obtuse edges.

Terminal and lateral plane angles may be obtained from a spherical triangle of which the angles are

(229.) $\quad \mathrm{A} = \mathrm{P,M}$
$$\mathrm{B} = \mathrm{P,T}$$
$$\mathrm{C} = \mathrm{M,T};$$

and of which the sides are

$$a = caf$$
$$b = baf$$
$$c = bac.$$

Terminal edges B and C unequal, B and F equal, C and D equal.

Lateral edges equal.

(230.) Ratio of terminal edge D to lateral edge,
$$ab : af :: m : n.$$

(231.) Ratio of terminal edge F to lateral edge,
$$ac : af :: o : n;$$

whence $\mathrm{D} : \mathrm{F} :: m : o$.

To obtain the ratios of $m : n$ and of $o : n$, let

$b\,e$, $e\,f$, $b\,f$, be the edges of a plane a whose symbol is $\overset{i}{O}$.

(232.) A spherical triangle whose angles are

$$A = 180^\circ - P,a$$
$$B = P,T,$$
$$C = 180^\circ - T,a,$$

will give the side $c = a\,e\,b$
$$a = a\,e\,f;$$

whence as $b\,a\,e$ and $e\,a\,f$ are known, the angles $e\,b\,a$ and $e\,f\,a$ are known, and hence the ratios of the edges may be found.

(233.) The plane angles $a\,b\,f$ and $a\,f\,b$ may also be deduced from another spherical triangle whose angles are

$$A = 180 - P,a$$
$$B = P,M$$
$$C = 180 - M,a.$$

(234.) Ratio of $b\,a$ perpendicular on $b\,d$ to $a\,l$, perpendicular on $f\,g$,

$a\,h : a\,b :: \cos(b\,a\,e - 90^\circ) : R.$

(235.) $:: m \,.\, \cos(b\,a\,e - 90^\circ) : m\,R,$

and $a\,f : a\,l ::$ $\quad n\,R$ $\quad : n\,.\cos(e\,a\,f - 90^\circ),$

but $a\,b : a\,f ::$ $\quad m$ $\quad : n.$

(236.) $a\,h : a\,l :: n\,.\cos(b\,a\,e - 90^\circ) : n\,.\cos(e\,a\,f - 90^\circ).$

In the same manner it may be shown that

(237.) $a\,i : a\,k :: o\,.\cos\,.(b\,a\,e - 90^\circ) : n\,.\cos(b\,a\,f - 90^\circ).$

(238.) $a\,n : a\,r :: m\,.\cos(b\,a\,f - 90^\circ) : o\,.\cos(e\,a\,f - 90^\circ).$

Decrements on the Angles.

By a method analogous to that used for determining the ratios of the primary edges, the ratios of the edges of the defect occasioned by any Law of Decrement on an angle may be obtained; and these being divided by the ratios of the primary edges will give the Law of Decrement. If an edge of any plane belonging to *Mod.* a or b, or c, or d, be parallel to a diagonal of a primary plane it will result from a simple decrement, and its symbol will be $_{n}A$, $\overset{n}{A}$, or A_n, $_nE$, $\overset{n}{E}$ or E_n, $_nI$, $\overset{n}{I}$ or I_n, $_nO$, $\overset{n}{O}$ or O_n, according to the situation of the primary plane to whose diagonal its edge is parallel.

Decrements on the Edges.

(239.) $$\overset{n}{B},v = \frac{n\,.\cos(e\,a\,f - 90^\circ)\,.\sin(T,g + P,T - 180^\circ)}{m\,.\cos(b\,a\,e - 90^\circ)\,.\sin(180^\circ - P,g)}.$$

(240.) $$\overset{n}{C},v = \frac{n\,.\cos(b\,a\,f - 90^\circ)\,.\sin(P,f + P,M - 180^\circ)}{o\,.\cos(b\,a\,e - 90^\circ)\,.\sin(180^\circ - P,f)}.$$

(241.) $$\overset{n}{D},v = \frac{n\,.\cos(b\,a\,f - 90^\circ)\,.\sin(P,e - P,M)}{o\,.\cos(b\,a\,e - 90^\circ)\,.\sin(180^\circ - P,e)}.$$

(242.) $$\overset{n}{F}\,v = \frac{n\,.\cos(e\,a\,f - 90^\circ)\,.\sin(P,h - P,T)}{m\,.\cos(b\,a\,e - 90^\circ)\,.\sin(180^\circ - P,h)}.$$

(243.) $$\overset{n}{G},v = \frac{o\,.\cos(e\,a\,f - 90^\circ)\,.\sin(180^\circ - T,k)}{m\,.\cos(b\,a\,f - 90^\circ)\,.\sin(180^\circ - M,k)}.$$

(244.) $$\overset{n}{H},v = \frac{m\,.\cos(b\,a\,f - 90^\circ)\,.\sin(180^\circ - M,i)}{o\,.\cos(e\,a\,f - 90^\circ)\,.\sin(180^\circ - T,i)}.$$

The ratio of $m : n$ and $m : o$ may be immediately obtained from either of these equations when $v = 1$.

THE RHOMBOID.

The Rhomboid.

Fig. 166 to 122, and 132 to 137.

Crystallographical Elements.

(245.) Inclination of planes at the terminal edge differs in different minerals, and is denoted by P, P'

$$P,P'' = 180^\circ - P,P'.$$

(246.) Plane angle $b\,d\,a$ may be found from the equation

$$\cos \tfrac{1}{2}\,b\,d\,a = \frac{R\,.\cos 60^\circ}{\sin \frac{1}{2}\,P,P''}$$

whence $d\,a\,f = 180^\circ - b\,d\,a$ is known.

Edges equal.

(247.) Inclination of terminal edge to axis may be thus found:

$$\cos e\,d\,n = \frac{\cot 60^\circ\,.\cot \frac{1}{2}\,P,P'}{R}.$$

(248.) Inclination of oblique diagonal to axis may be obtained from the equation

$$\cos e\,d\,n = \frac{R\,.\cos \frac{1}{2}\,P,P'}{\sin 60^\circ},$$

whence $e\,d\,c = e\,d\,n + e\,d\,n$ is known,

and $d\,f\,i = 180^\circ - e\,d\,c.$

(249.) But $e\,d\,c$ may be found directly from the equation

$$\cos e\,d\,c = \frac{R\,.\cos P,P}{\sin \frac{1}{2}\,P,P'}.$$

(250.) Ratio of edge to half oblique diagonal,

$$d\,b : d\,e :: R : \cos \tfrac{1}{2}\,b\,d\,a,$$
$$:: 1 : \frac{\cos 60}{\sin \frac{1}{2}\,P,P'}.$$

(251.) Ratio of edge to half horizontal diagonal,

$$d\,b\,.\,b\,e :: R : \sin \tfrac{1}{2}\,b\,d\,a,$$

$$:: 1 : \frac{\{(\sin \frac{1}{2}\,P,P')^2 - (\cos 60^\circ)^2\}^{\frac{1}{2}}}{\sin \frac{1}{2}\,P,P'},$$

for $(\sin \frac{1}{2}\,b\,d\,a)^2 = R^2 - (\cos \frac{1}{2}\,b\,d\,a)^2$

$$R^2 - \frac{R^2\,(\cos 60^\circ)^2}{(\sin \frac{1}{2}\,P,P')^2}$$
$$= \frac{R^2\,\{(\sin \frac{1}{2}\,P,P')^2 - (\cos 60^\circ)^2\}}{(\sin \frac{1}{2}\,P,P')^2}$$

(252.) Ratio of edge to one-third of axis,

$$d\,b : d\,n :: R : \cos b\,d\,n$$
$$:: 1 : \frac{\cot 60\,.\cot \frac{1}{2}\,P,P'}{R^2}.$$

Axis $= 3\,d\,n$:

for the edges being equal, and the terminal angles equal, the plane $a\,b\,c$ is perpendicular to the axis; therefore $e\,n\,c$ is also perpendicular to it.

Let $f\,o$ be parallel $e\,n$, and because $d\,e = e\,f$, $\therefore d\,n = n\,o$, but $e\,n = f\,o$, whence $o\,i = d\,n$,

and $\quad d\,n + n\,o + o\,i = 3\,d\,n,$

and $\quad e\,n = 2\,e\,n.$

Simple Decrements on the Angles.

(253.) $\overset{v}{\mathrm{A}}$, $\quad v = \dfrac{\sin\frac{1}{2}\,\mathrm{P,P'} \,.\, \sin(\mathrm{P},b - e\,d\,e)}{\cos 60^\circ \,.\, \sin(180^\circ - \mathrm{P},b)}$.

(254.) $\quad = \dfrac{\sin\frac{1}{2}\,\mathrm{P,P'} \,.\, \sin(\mathrm{P},c' - e\,d\,c)}{\cos 60^\circ \,.\, \sin(180^\circ - \mathrm{P},c')}$.

(255.) $\overset{v}{\mathrm{O}}$, $\quad v = \dfrac{\sin\frac{1}{2}\,\mathrm{P,P'} \,.\, \sin(\mathrm{P},e' - d\,f\,i)}{\cos 60^\circ \,.\, \sin(180^\circ - \mathrm{P},e')}$.

And similar expressions in which P,g, or P,i, or P,l are respectively substituted for P,e, will give the laws producing the planes g, i, and l.

(256.) When the Rhomboid is *acute*,

$$\overset{v}{\mathrm{E}}, \quad v = \frac{\sin e'\,d\,a \,.\, \mathrm{R}}{\sin\frac{1}{2}\,a\,d\,b \,.\, \tan(180^\circ - \mathrm{P},h)}.$$

For let a line passing through $i\,a$ be produced to l, and let $d\,l$ be perpendicular to $l\,a$, and $f\,m$, $b\,m$ respectively parallel to $a\,l$, $d\,l$;

$$e'\,b : b\,f :: \sin\tfrac{1}{2}\,a\,d\,b : \mathrm{R},$$
$$b\,m : b\,f :: \cos(90^\circ - e'\,d\,a) : \mathrm{R},$$
$$:: \sin e'\,d\,a : \mathrm{R},$$
$$\therefore e'\,b : b\,m :: \sin\tfrac{1}{2}\,a\,d\,b : \sin e'\,d\,a.$$

(257.) When the Rhomboid is *obtuse*,

$$e'\,b : b\,m :: \sin\tfrac{1}{2}\,a\,d\,b : \cos(e'\,d\,a - 90^\circ),$$

and $$v = \frac{\mathrm{R} \,.\, \cos(e'\,d\,a - 90^\circ)}{\sin\frac{1}{2}\,a\,d\,b \,.\, \tan(180^\circ - \mathrm{P},h)}.$$

It is manifest that the planes replacing the angle at E are similar to those at O but in an inverted position, and that the Laws of Decrement producing any of the planes of *Mod.* e, f, g, h, i, k, l, m, might with equal propriety be referred either to E or O. It will, however, be convenient to refer the planes of *Mod.* h to the angle E, and all the others to the angle O.

Decrements on the Edges.

(258.) The Laws of Decrement on the terminal edges may be found as follows:

$$\overset{v}{\mathrm{B}}, \quad v = \frac{\sin(\mathrm{P},o - \mathrm{P,P''})}{\sin(180^\circ - \mathrm{P},o)}.$$

(259.) Those on the lateral edges may be thus known:

$$\overset{v}{\mathrm{D}}, \quad v = \frac{\sin(\mathrm{P},q - \mathrm{P,P''})}{\sin(180^\circ - \mathrm{P},q)}.$$

Intermediary Decrements.

When these affect the terminal angles, they produce the planes of *Mod.* d. And when they modify the lateral angles, they produce the planes f, k, and m.

The angles of the spherical triangle required to determine the laws of intermediary decrements on the terminal solid angles, are

$$\mathrm{A} = 180^\circ - \mathrm{P},d,$$
$$\mathrm{B} = \mathrm{P,P'},$$
$$\mathrm{C} = 180^\circ - \mathrm{P},d;$$

and those required for the decrements on the lateral solid angles, are

$$\mathrm{A} = 180^\circ - \mathrm{P} \text{ on } f, \text{ or } k, \text{ or } m,$$
$$\mathrm{B} = \mathrm{P,P''},$$
$$\mathrm{C} = 180^\circ - \mathrm{P''} \text{ on } f, \text{ or } k, \text{ or } m.$$

(260.) The indices p, q, r of the planes f are found to be in the following constant ratio to each other:

$$p = q\,r,$$
$$= r + 1,$$
$$r > 1;$$
$$\therefore \text{ if } r = 2,\ q = 3, \text{ and } p = 6.$$

This arises from the condition that the intersection of f and f' is parallel to the axis of the Rhomboid; and the ratio may be easily obtained by considering the planes P, P′, P″ as coordinate planes, and finding the equations of the traces of the plane c and one of the planes f on the plane P″.

From these equations, r being supposed the same in both, the values of p and q are known.

The following formulæ will be found useful in the examination of Crystals belonging to this form.

P,a being given, to find P,P′ and conversely.

(261.) $\quad \cos\frac{1}{2}\,\mathrm{P,P'} = \dfrac{\cos 30^\circ \,.\, \sin \mathrm{P},a}{\mathrm{R}}$

(262.) $\quad \sin \mathrm{P},a = \dfrac{\mathrm{R} \,.\, \cos\frac{1}{2}\,\mathrm{P,P'}}{\cos 30^\circ}$.

n,n′ being given, to find P,P′ and conversely.

(263.) $\quad \cot\frac{1}{2}\,\mathrm{P,P'} = \dfrac{\mathrm{R} \,.\, \cos\frac{1}{2}\,n,n'}{\cos 60^\circ}$.

(264.) $\quad \cos\frac{1}{2}\,n,n' = \dfrac{\cot\frac{1}{2}\,\mathrm{P,P'} \,.\, \cos 60^\circ}{\mathrm{R}}$.

For $e\,d\,n$ is the inclination of the oblique diagonal on the axis of the Rhomboid whose planes are n, n', n'', &c.

$$\cos e\,d\,n = \frac{\mathrm{R} \,.\, \cos\frac{1}{2}\,n,n'}{\sin 60^\circ},$$

and by equating this value of $\cos e\,d\,n$ with that given by (247.), (263.) and (264.) are obtained.

(265.) A series of Rhomboids more obtuse than the primary, of which *Mod.* n may be regarded as the first member, might be produced by the successive truncation of the terminal edges of the derived Rhomboids. And another series more acute than the primary, of which *Mod.* g may be regarded as the first member, might also be produced by planes on the angles of each successive Rhomboid, which should intersect the planes P in parallel lines.

The relations of any member of *either* of these to the primary may be found as follows.

Obtuse Series.

Let P denote the primary Rhomboid,
1, the 1st derived, corresponding to *Mod.* n,
2, the 2d derived,
m, the m^{th} derived,
P,P′, the inclination of the primary planes,
$\mathrm{P,P'}_m$, the corresponding angle of the m^{th} derived Rhomboid.

The line corresponding to $e\,n$ in P, is in $1 = 2\,e\,n$,
$2 = 2^2\,e\,n$,
$m = 2^m\,e\,n$.

Let $e\,d\,n$ of 1 be denoted by $e\,d\,n_1$,
of 2 . . . . $e\,d\,n_2$,
of m . . . . $e\,d\,n_m$;

$$d\,n :: e\,n :: 1 : \tan e\,d\,n,$$
$$d\,n :: 2^m\,e\,n :: 1 : \tan e\,d\,n_m:$$

hence $\tan e\,d\,n = \dfrac{\tan e\,d\,n_m}{2^m}$;

but $\cos e\,d\,n = \dfrac{1}{\{1 + (\tan e\,d\,n)^2\}^{\frac{1}{2}}}$;

hence $(\tan e\,d\,n)^2 = \dfrac{(\sin 60^\circ)^2 - (\cos \frac{1}{2} P,P')^2}{(\cos \frac{1}{2} P,P')^2}$

$= \dfrac{(\sin 60^\circ)^2 - (\cos \frac{1}{2} P,P'_m)^2}{2^{2m}(\cos \frac{1}{2} P,P')^2}.$

(266.) From these two values of $(\tan e\,d\,n)^2$ the following equations are derived:

$$(\cos \tfrac{1}{2} P,P')^2 = \frac{(\cos \frac{1}{2} P,P'_m)^2 . (\sin 60^\circ)^2 . 2^{2m}}{(\sin 60^\circ)^2 + (\cos \frac{1}{2} P,P'_m)^2 . (2^{2m} - 1)}.$$

(267.) $(\cos \frac{1}{2} P,P'_m)^2 =$

$$\frac{(\cos \frac{1}{2} P,P')^2 . (\sin 60^\circ)^2}{2^{2m}\{(\sin 60^\circ)^2 - (\cos \frac{1}{2} P,P')^2\} + (\cos \frac{1}{2} P,P')^2};$$

(268.) $2^{2m} = \dfrac{(\cos\frac{1}{2} P,P')^2\{(\sin 60^\circ)^2 - (\cos\frac{1}{2} P,P'_m)^2\}}{(\cos\frac{1}{2} P,P'_m)^2\{(\sin 60^\circ)^2 - (\cos\frac{1}{2} P,P')^2\}}$

$= a$;

and $m = \dfrac{\log a}{2 \log 2}.$

Acute Series.

Here the 1st derived corresponds to *Mod. g*, and the

$e\,n$ of P is in $1 = 2^{-1}\,c\,n$,

$2 = 2^{-2}\,c\,n$,

$m = 2^{-m}\,c\,n$,

and the preceding formulæ may be applied to this series by substituting 2^{-2m} for 2^{2m}.

Hence, when any two of the quantities P,P', P,P'_m, and m are known, the third may be found.

(269.) The Laws of Decrement which would immediately produce the successive members of the obtuse and acute series from the primary Crystal, may be readily found from the relations of the principal sections of the derived Rhomboids to that of the primary.

Of the obtuse series the symbol of the

1st is	$\overset{\frac{0}{1}}{A}$ or $\overset{1}{B}$	5th is	$\overset{\frac{10}{11}}{A}$
2d is	$\overset{\frac{2}{1}}{A}$	6th is	$\overset{\frac{22}{21}}{A}$
3d is	$\overset{\frac{2}{3}}{A}$		
4th is	$\overset{\frac{6}{5}}{A}$	mth is	$\overset{\frac{2^m+2(-1)^m}{2^m+(-1)^{m-1}}}{A}$

The symbols of the acute series are as follows:

1st is	$\overset{\frac{1}{1}}{O}$	5th is	$\overset{\frac{21}{11}}{O}$
2d is	$\overset{\frac{3}{1}}{O}$	6th is	$\overset{\frac{43}{21}}{O}$
3d is	$\overset{\frac{5}{3}}{O}$		
4th is	$\overset{\frac{11}{5}}{O}$	mth is	$\overset{\frac{2^{m+1}+(-1)^m}{2^m+(-1)^{m+1}}}{O}$

The law of each series is obvious, and the general terms of the mth easily deduced.

Either of the dihedral angles a,b, a,c, a,d, or a,a', (fig. 133,) being given, to find either of the others.

(270.) $\cos \frac{1}{2} a,b = \dfrac{R . \cos \frac{1}{2} a,c}{\tan 60^\circ}.$

(271.) $= \dfrac{\cos 60^\circ . \sin (a,d - 90^\circ)}{R}.$

(272.) $\cos \frac{1}{2} a,c = \dfrac{\sin 60^\circ . \sin (a,d - 90^\circ)}{R}.$

(273.) $= \dfrac{\cos \frac{1}{2} a,b . \tan 60^\circ}{R}.$

(274.) $\sin (a,d - 90^\circ) = \dfrac{R . \cos a,b}{\cos 60^\circ}.$

(275.) $= \dfrac{R . \cos a,c}{\sin 60^\circ}.$

To find the Law of Decrement which gives a regular hexagonal pyramid.

Pyramids of this kind might result from *Mod. d, h, k, m,* or *o.*

(276.) Let fig. 134 represent a section of one of these pyramids perpendicular to the axis, in which $a\,b$, $b\,c$ correspond to two horizontal diagonals of fig. 132.

From the assumed regularity of the pyramid this section must be a regular hexagon. Hence the angle $a\,f\,b = 120^\circ = f\,b\,g = b\,g\,c$.

From the symmetry of the figure the triangles $a\,b\,g$ and $b\,o\,f$ are similar, and $f\,b$ is parallel to $a\,g$. But $a\,g$ bisects $b\,c$, and any planes therefore belonging to a regular hexagonal pyramid must cut the horizontal diagonals $a\,b$, $b\,c$, in the ratio of $2 : 1$.

Whence any planes which shall cut the plane $a\,b\,c$, fig. 135, parallel to the line $a\,n$, will produce these pyramids.

Let $a\,i\,h$ (fig. 135) be a plane of *Mod. d*, intersecting $a\,b\,c$ in $a\,n$.

Let t (fig. 135 and 136) represent the terminal solid angle of the Rhomboid, and let $t\,b : t\,h :: 1 : 2$.

To find $t\,i$, we have in fig. 136,

$$\begin{aligned} t\,h &= 2\,t\,b \\ b\,n &= n\,c \\ k\,b &= b\,c \\ k\,h &= t\,b = t\,c \\ &= t\,a, \text{ fig. } 135; \end{aligned}$$

$\therefore\ k\,h : i\,c :: k\,n : n\,c$

$:: 3 : 1$;

$\left.\begin{aligned} \therefore\ t\,a : t\,i &:: 3 : 2 \\ t\,a : t\,h &:: 3 : 6 \end{aligned}\right\}$ fig. 135.

Hence the indices of this plane would be (6 3 2), and the indices of the plane $a\,h'\,i'$ (fig. 135) would be (6 4 3.)

(277.) We may imagine a series of planes passing through $a\,n$ to lie within two limits. The one the plane $a\,b\,c$, and the other the plane p, (fig. 121.)

The edge $t\,h$ might be supposed to be lengthened until it becomes infinite, when the planes of *Mod: o* would be produced.

The point h may next be conceived to approach towards the axis, while the plane o turning on the line $a\,n$ assumes successively the positions of *Mod. h, f,* and *m*.

In *Mod. f* the edge $t\,h$ becomes parallel to the axis of the Rhomboid, producing a prism with twelve sides.

As the condition of producing a regular hexagonal pyramid is that its planes shall cut the horizontal diagonals in the ratio of $2 : 1$, there might evidently be a

Crystallography.

series of such pyramids belonging to *Mod. d, h, k,* and *m*; but only one can result from *Mod. o*, and one other from *Mod. h*. That from *Mod. o* must be produced by a decrement of two rows, and must have for its symbol $\dot{B}$, and that from *Mod. h* by three rows, and must have for its symbol $\dot{E}$.

For let $d\,o\,g$ (fig. 137) represent one of the planes of *Mod. h*, we have $p\,b : b\,n :: 1 : 2$,

whence $a\,p : p\,b :: a\,d\,(= d\,b) : o\,b$,

$:: 3 : 1$.

Hexagonal Prism.

(278.) It may occasionally be convenient on account of the greater simplicity of the Laws of Decrement, to consider the regular hexagonal prism as an independent primary form, although it is derivable from the Rhomboid by the joint effect of *Mod. a* and *e*, or *a* and *p*.

The Laws of Decrement may then be determined as follows:

Single Planes, a, on the angles.

Let the terminal plane be denoted by P, and the lateral planes by M.

Let each terminal angle be denoted by A, each terminal edge by B, and each lateral edge by G.

Let $B : G :: m : n$,

and the edges of the defect will be as

$$p\,m : 2\,r\,n :: \sin(P,a - 90°) : \sin(180° - P,a).$$

Two Planes, b, on the angles.

The law may be found by the general method before explained.

Single Planes, c, on the terminal edges.

The edges of the defect will be as

$$p\,m\,\frac{\sqrt{3}}{2} : r\,n :: \sin(P,b - 90°) : \sin(180° - P,b).$$

Planes, e, on the lateral edges.

The edges of the defect will be as

$$p : r :: \sin(180° - M,e) : \sin(M,e - 60°).$$

(279.) Having thus shown how the laws of decrement may be determined when the inclination of the secondary plane to the primary is known, it is now proposed to discover that inclination from the known elements of the primary form, and the Law of Decrement.

Let it be required to find the angle at which a plane whose symbol is $\dot{A}$ inclines on a primary plane.

1st. Suppose this plane to occur on the square prism:

$$v = \frac{p}{r} = \frac{n\,R\,\sqrt{2}}{m\,.\tan(180°-P,a)}.$$

$$(280.)\quad \therefore \tan(180° - P,a) = \frac{r\,n\,R\,\sqrt{2}}{p\,m}.$$

2d. If it occurs on the right rhombic prism,

$$v = \frac{p}{r} = \frac{n\,R^2}{m\,.\cos\tfrac{1}{2}M,M'\,.\tan(180° - P,a)}.$$

$$(281.)\quad \therefore \tan(180° - P,a) = \frac{r\,n\,R^2}{p\,m\,.\cos\tfrac{1}{2}M,M'}.$$

3d. If the plane whose inclination to the primary is required, have for its symbol $\dot{H}$, and the primary form be a right rhombic prism,

The Rhomboid.

$$v = \frac{p}{r} = \frac{\sin(180 - M,g)}{\sin(M,g - M,M')};$$

whence it will be found that

$$(282.)\quad \tan M,g = \frac{p\,R\,.\sin M,M'}{p\cos.\,M,M' - r\,R}.$$

And in other cases of simple decrements, the dihedral angles which have been used to determine the laws, may be found by analogous methods when the laws are known.

The inclinations of the primary planes to planes produced by intermediary decrements may also be found from the known laws, and from the plane angles of some of the primary or secondary planes.

(283.) Professor Whewell of Cambridge has, in a Paper inserted in the *Philosophical Transactions* for 1825, given a general form to the problem of finding the inclination or dihedral angle of any two planes from their indices, and of finding the indices from the given angle.

But general and elegant as the solutions given in this Paper are, we are induced to believe that the more direct methods already explained in this Treatise, will, from their greater simplicity, and the comparative ease with which they may be applied, be found in most cases more serviceable to the practical Mineralogist.

In order, however, to place before the reader the most comprehensive and entire view of the mathematical relations of Crystals which has yet been given, we insert the following brief abstract of Mr. Whewell's communication to the Royal Society, referring the reader to the Paper itself for the details of its application to particular cases.

Let a solid angle, denoted in the Tables of Modifications by A of the cube, or square prism, or right rhombic prism, or rhomboid, or O of the oblique rhombic prism, or doubly oblique prism, be regarded as the origin of a system of coordinates, of which the three adjacent edges are the axes.

Let the dihedral angle at the axis $x = \alpha$,

.... $y = \beta$,

.... $z = \gamma$,

and the angle formed by the axis

x and a perpendicular on the plane $y\,z = \delta$,

y .... $x\,z = \epsilon$,

z .... $x\,y = \zeta$.

Then let $\cos\alpha = a$, $\cos\beta = b$, $\cos\gamma = c$,
$\cos\delta = d$, $\cos\epsilon = e$, $\cos\zeta = f$,

and let θ be the dihedral angle of two planes whose equations are

$$\frac{x}{p} + \frac{y}{q} + \frac{z}{r} = 0,^*$$

$$\frac{x}{p'} + \frac{y}{q'} + \frac{z}{r'} = 0.$$

The planes expressed by these equations are supposed to pass through the origin, and they may be expressed generally by the symbols

* Professor Whewell has used the letters *h, k,* and *l* to denote the portions of the edges intercepted by secondary planes, and has adopted *p, q,* and *r* to denote the *reciprocals* of those portions. Having, however, in this Treatise used *p, q,* and *r* to express Mr. Whewell's lines *h, k* and *l*, we have substituted $\frac{1}{p}$, $\frac{1}{q}$, and $\frac{1}{r}$ for *p, q,* and *r* in his equations.

$$(p\ q\ r),\ (p'\ q'\ r');$$

the first index always referring to the axis x, the second to y, and the third to z.

According to the law of symmetry, the solid angle which is assumed as the origin of the system of co-ordinates may in the cube and rhomboid be replaced by six planes, which would require to be denoted by six distinct symbols. And these would be supplied by permuting the three indices, thus, (p, q, r) (p, r, q) (q, r, p) (r, q, p) (r, p, q) (q, p, r), the order of these symbols being that in which the planes they represent occur on the Crystal.

When *all* the indices are to be permuted, they may be written in the symbol of each plane with commas between them, thus, (p, q, r).

And every *particular* symbol in which the three indices are separated by commas, is known to belong to a *general* symbol, in which *all* those indices are subject to permutation.

On the other primary forms there cannot occur more than two planes upon any solid angle, and in this case only two of the indices, as p and q, are to be permuted, and the form of the particular symbol becomes $(p, q; r)$, the semicolon denoting that r is not subject to permutation. The symbol of the two planes would in this case be $(p, q;\ r)$ $(q, p; r)$.

And when, as in the doubly oblique prism, the law of symmetry requires only one plane on each solid angle, the indices are not subject to any permutation; a condition which is expressed by separating them by semicolons, thus, $(p; q; r)$.

Planes which replace any angle of a Crystal may be referred to that which has been assumed as the origin of the coordinates; but in this case the angles made by a transferred plane with the coordinate planes will be the supplements of its inclinations to the primary planes adjacent to it, and one or more of the indices of the transferred plane will be negative, as $(p\ -q\ -r)$ or $(-p\ q\ r)$.

Planes replacing any of the edges may also be referred to the assumed coordinates, but one index will then be 0, and one or both of the others may be positive or negative; and the *general* symbol might be $(p\ 0\ r)$; observing in *particular* symbols to add the commas or semicolons as required by the law of symmetry.

The symbol of the primary plane of the

$$\begin{array}{ll} y\,z \text{ is} & (1, 0, 0) \\ x\,z & (0, 1, 0) \\ x\,y & (0, 0, 1). \end{array}$$

If all the indices of a symbol be multiplied or divided by any quantity, the character of the plane denoted by the altered symbol will not be changed, but its new position will be parallel to that indicated by the original symbol.

The dihedral angle, or the inclination of two planes whose symbols are (p, q, r) (p', q', r') has been denoted by θ, and we may express the angle made by (p, q, r) and (p'', q'', r'') by θ'.

The angle θ may be found from the following equations, observing that in the cube and the rhomboid the primary edges are equal; in the square and right and oblique rhombic prisms the terminal edges are equal, but differing from the lateral ones; and that in the doubly oblique prisms the three edges adjacent to O are unequal.

We shall suppose the planes whose angle is required, to occur on each of the classes of primary forms.

1st. *On the cube and square prism,* where

$$\alpha = \beta = \gamma = 90^\circ,$$

On the Parallelisms of the Edges of Crystals.

(297.) The resources of Crystallography in determining the Laws of Decrement by which secondary planes are produced, are not limited to the methods already explained. In certain cases those laws may be inferred from Parallelisms among some of the edges of combination of the different planes. Thus the Parallelism of the terminal edge of the plane d of the square prism to the diagonal of the terminal plane, implies a decrement by one row on the lateral edge of the prism.

This is one of the most simple cases that can occur. Others, however, of a much more complicated nature may be determined from similar considerations.

The following are the principal classes of Parallelisms that occur among the edges of Crystals.

For the sake of generality, the doubly oblique prism, fig. 95, has been used in the diagrams about to be referred to.

(298.) When two adjacent edges are replaced by single planes resulting from any Law of Decrement, and the solid angle between them is also replaced by a single plane produced by the same law, the plane on the angle is a parallelogram, as in fig. 138.

In this figure the plane on the angle intersects the lateral planes parallel to their intersection by the planes on the edges. The indices of both must therefore be similar. And the symbols $\dot{D}$, $\dot{O}$, $\dot{F}$, may be said to express the conditions for rendering the plane on the angle a parallelogram.

When the replaced edges are *similar*, as they are in the regular forms, the plane replacing the angle becomes a rhomb.

(299.) When a plane on the angle is cut in parallel lines by planes on the edges, the decrement *in height* of the three planes being the same, as at a, b, c, d, fig. 139, the decrement *in breadth* of the plane on the angle will be equal to the sum of the decrements *in breadth* of the planes on the edges.

If in this figure the planes on the edges are represented by $\overset{r}{D}$, $\overset{r'}{F}$, it will be found that the condition for rendering the edges of the plane on the angle parallel, is that its symbol should be $\overset{r+r'}{O}$.

(300.) When a plane replacing an edge is intersected in parallel lines by planes replacing the adjacent solid angles, and produced by the same Law of Decrement, as at a, b, c, d, fig. 140 and 141, the planes on the edge and the planes on the angles must intersect two of the primary planes in parallel lines.

In fig. 140 the planes on the angles intercept the lateral planes parallel to their intersection by the plane on the edge. The conditional indices for which may be readily found from what has been before stated. When the angles are *similar*, as in fig. 65, the symbols might be $\ddot{B}$, $\dot{A}$; $\hat{B}$, A_r; or $\overset{y}{B}$, $(B_p\ B'_q\ G_r)$; and they will be analogous to these for the other primary forms.

Crystallography.

Fig. 141 shows that the indices relating to the terminal edges must be the same in the symbols of the three planes.

(301.) When the intersection of planes on two adjacent terminal edges is parallel to the intersection of one of those with a plane on the lateral edge, as in fig. 142, the relation of the plane on the lateral edge to those on the terminal edges will be as follows:

Let the symbol of the plane on the terminal edge adjacent to the lateral truncated edge be $\frac{p}{r}$, and that of the plane truncating the second terminal edge be $\frac{p'}{r}$, the symbol of the plane on the lateral edge will be $\frac{p}{p'}$, for $a\,b$ will then be parallel to $c\,d$, and $a\,c$ to $c\,f$.

(302.) Where an angle is replaced by a single plane which is intersected in parallel lines by two planes on the same angle resulting from the same law, as in fig. 143, the relation of the indices may be found as follows.

The edge $f\,s$ is the intersection of two planes $c\,a\,s$, $m\,k\,s$, on the angle c.

The plane $g\,h\,s$ evidently coincides with the edge $f\,s$, and if it be supposed to move parallel to itself until it reaches the position $n\,o\,p$, it must be intersected in the parallel lines $t\,v$, $u\,x$, by the planes $c\,a\,s$, $m\,k\,s$.

Let $e\,m$ and $e\,c$ represent p molecules.

$e\,a$ and $e\,k$ .... q

$e\,s$.............. r

To determine the law of the plane $g\,h\,s$ we require the ratio of $e\,h$ to $e\,s$. But as $e\,s$ is assumed to represent r molecules, it is only necessary to determine $e\,h$ in terms of p and q.

In fig. 141 let $e\,c = p$, $e\,k = q$,

and we shall have $\qquad e\,h = \dfrac{2\,p\,q}{p+q}$.

For from the nature of the figure

$$m\,d = d\,c$$

$$\text{and } a\,b = b\,k;$$

and by similar triangles we have

$$c\,e : k\,e :: p : q :: d\,c : b\,k,$$
$$:: d\,f : f\,b,$$
$$:: d\,e : b\,e;$$

$$\text{whence } d\,f : d\,f + f\,b\,(= d\,b) :: p : p+q,$$
$$d\,e : d\,e - b\,e\,(= d\,b) :: p : p-q,$$
$$\text{and } d\,e : d\,f :: p+q : p-q;$$
$$\therefore\ d\,e : d\,e - d\,f\,(= f\,e) :: p+q : 2\,q$$
$$:: p : \frac{2\,p\,q}{p+q}$$
$$:: e\,c : e\,h.$$

Hence the index of the planes $g\,h\,s$, or $n\,o\,p$, becomes $\dfrac{2\,p\,q}{r\,(p+q)}$.

The preceding are, however, only particular cases of the following general expression given by Professor Whewell in the Paper already referred to.

Parallelisms of Edges of Crystals.

Let the plane whose indices are $(p_2\,q_2\,r_2)$ truncate the intersection of the planes $(p_1\,q_1\,r_1)$ and $(p_3\,q_3\,r_3)$, and we have

$$(303.)\quad \frac{1}{p_2}\left(\frac{1}{q_1 r_3} - \frac{1}{q_3 r_1}\right) + \frac{1}{q_2}\left(\frac{1}{p_3 r_1} - \frac{1}{p_1 r_3}\right) + \frac{1}{r_2}\left(\frac{1}{p_1 q_3} - \frac{1}{p_3 q_1}\right) = 0.$$

If the planes 1 and 3 are produced by the same law, then $p_1 = q_3$, $q_1 = p_3$, and $r_1 = r_3$; and

$$(304.)\qquad \frac{p_2\,q_2}{(p_2+q_2)\,r_2} = \frac{p_1\,q_1}{(p_1+q_1)\,r_1}.$$

If in this equation $p_2 = q_2$, and $r_2 = r_1$, it becomes

$$(305.)\qquad p_2 = \frac{2\,p_1\,q_1}{(p_1+q_1)},$$

and corresponds to (302.)

If planes 1 and 3 are on the angles, and plane 2 on the edge between them, as in fig. 140, p_1 is negative and $p_2 = \infty$, and

$$(306.)\qquad \frac{q_2}{r_2} = \frac{\dfrac{p_1}{r_1} + \dfrac{p_3}{r_3}}{\dfrac{p_1}{q_1} + \dfrac{p_3}{q_3}}.$$

If, as in (300.), $q_1 = q_3$ and $r_1 = r_3$,

$$(307.)\qquad \frac{q_2}{r_2} = \frac{q_1}{r_1}.$$

If planes 1 and 2 are on adjacent terminal edges, and 3 on a lateral edge, as in fig 142, then $r_1 = r_2$, $q_1 = \infty$, $p_2 = \infty$, $r_3 = \infty$, and the equation corresponds to (301.)

$$(308.)\qquad \frac{p_1}{q_2} = \frac{p_3}{q_3}.$$

If planes 1 and 3 are on adjacent edges, and 2 on the angle between them, then $p_1 = \infty$, and $q_3 = \infty$, and

$$(309.)\qquad \frac{1}{p_2}\cdot\frac{p_3}{r_3} + \frac{1}{q_2}\cdot\frac{q_1}{r_1} - \frac{1}{r_2} = 0.$$

If, as in (299.), $p_2 = q_2$, and $r_1 = r_2 = r_3$, then

$$(310.)\qquad p_2 = p_3 + q_1.$$

If $p_3 = q_1$ and $r_2 = r_1$, then

$$(311.)\qquad \frac{p_2}{r_2} = \frac{2\,q_1}{r_1}.$$

(312.) Mr. Levy has given the following formulæ in a Paper in the VIth volume of the *Edinburgh Philosophical Journal*, p. 227, on the method of finding the law of decrement of any secondary plane, modifying any parallelopiped, whenever two of the edges of that plane, *not being parallel to each other*, are parallel to two edges of the Crystal whose relations to the primary edges are known.

Let p_5, q_5, r_5, be the unknown indices of the new plane, which may be called plane 5. Let p_1, q_1, r_1, and p_2, q_2, r_2, be the known indices of two planes to whose intersection one edge of plane 5 is parallel. And p_3, q_3, r_3, and p_4, q_4, r_4, the known indices of two other planes, to whose intersection another edge of plane 5 is parallel, and

Crystallography.

(313.) $$\frac{p_5}{r_5}=\begin{array}{c}\left(\frac{1}{r_1\,p_2}-\frac{1}{r_2\,p_1}\right)\cdot\left(\frac{1}{q_3\,r_4}-\frac{1}{r_3\,q_4}\right)\\ \hline \left(\frac{1}{r_1\,p_2}-\frac{1}{r_2\,p_1}\right)\cdot\left(\frac{1}{q_3\,p_4}-\frac{1}{p_3\,q_4}\right)\\ +\left(\frac{1}{q_1\,r_2}-\frac{1}{q_2\,r_1}\right)\cdot\left(\frac{1}{p_3\,r_4}-\frac{1}{p_4\,r_3}\right)\\ \hline +\left(\frac{1}{q_1\,p_2}-\frac{1}{q_2\,p_1}\right)\cdot\left(\frac{1}{p_3\,r_4}-\frac{1}{p_4\,r_3}\right)\end{array}$$

(314.) $$\frac{q_5}{r_5}=\begin{array}{c}\left(\frac{1}{r_1\,q_2}-\frac{1}{r_2\,q_1}\right)\cdot\left(\frac{1}{p_3\,r_4}-\frac{1}{r_3\,p_4}\right)\\ \hline \left(\frac{1}{r_1\,q_2}-\frac{1}{r_2\,q_1}\right)\cdot\left(\frac{1}{p_3\,q_4}-\frac{1}{q_3\,p_4}\right)\\ +\left(\frac{1}{p_1\,r_2}-\frac{1}{p_2\,r_1}\right)\cdot\left(\frac{1}{q_3\,r_4}-\frac{1}{q_4\,r_3}\right)\\ \hline +\left(\frac{1}{p_1\,q_2}-\frac{1}{p_2\,q_1}\right)\cdot\left(\frac{1}{q_3\,r_4}-\frac{1}{q_4\,r_3}\right)\end{array}$$

If the instersection of the planes 1 and 2 be parallel to a diagonal of the primary form, the plane 5 will be parallel to the same diagonal; in this case two of the indices will be equal. If $p_1 = q_1$, and $p_2 = q_2$, the values of $\frac{p_5}{r_5}$ and $\frac{q_5}{r_5}$ become equal; and by reducing the above equations, after the necessary substitutions are made, the following will result:

(315.) $$\frac{p_5}{r_5}=\frac{q_5}{r_5}=\frac{\frac{1}{q_3\,p_4-p_3\,q_4}}{\left(\frac{1}{q_3\,r_4}-\frac{1}{r_3\,q_4}\right)+\left(\frac{1}{p_3\,r_4}-\frac{1}{r_3\,p_4}\right)}.$$

If the intersection of the planes 1 and 2 be parallel to an edge of the primary form, the plane 5 will be parallel to the same edge, and one of the indices will be infinite. If r_1 and r_2 become infinite, the values of $\frac{p_5}{r_5}$, $\frac{q_5}{r_5}$, become infinite also. But if equation 1 be divided by 2, the following equation will be obtained, which does not contain the indices of planes 1 and 2, but gives the values of p_5 and q_5 in terms of the indices of planes 3 and 4,

(316.) $$\frac{p_5}{q_5}=\frac{\frac{1}{q_3\,r_4}-\frac{1}{q_4\,r_3}}{\frac{1}{p_3\,r_4}-\frac{1}{p_4\,r_3}}.$$

The facilities afforded by the Parallelisms of Edges in determining the relations of Crystals will be shown by the following examples.

(317.) Fig. 145 is one of the forms of what is termed by Mineralogists muriate of mercury, and it is also the crystalline form of calomel.

The edges of c being rendered parallel by a, both planes must have the same index, and the respective symbols may be $\overset{1}{B}$, and $\overset{1}{A}$.

(318.) Fig. 146 is the form of a Crystal of sulphate of nickel.

In this figure the edges of the plane $a1$ produced by the intersection of c and c' are parallel, and those of c produced by the intersection of $a2$ and $a'2$ are also parallel. Hence the Laws of Decrement producing all these planes are known.

Parallelisms of Edges of Crystals.

For if $\overset{1}{B}$ be the symbol of c, then $\overset{1}{A}$ must be that of $a2$, and $\overset{2}{A}$ that of $a1$.

(319.) Fig. 147 represents a Crystal of scheelate of soda, the primary form of which is a doubly oblique prism.

The planes g and e evidently replace two of the terminal edges, and the plane e is intersected in parallel lines by g and i. If, therefore, we assume the symbol of the plane i to be $\overset{1}{H}$, e and g must be represented by $\overset{1}{B}$ and $\overset{1}{D}$.

(320.) Fig. 148 is a Crystal of oxide of tin, the planes of which may be determined as follows:

Let $c1$ be assumed to result from a decrement by 1 row on the terminal edge of a square prism, and its symbol will be $\overset{1}{B}$.

$a1$ must then be represented by $\overset{1}{A}$, and

$c2$ by $\overset{\frac{1}{2}}{B}$.

$c3$ is known from measurement to result from a decrement by 5 rows in height, and to have for its symbol $\overset{\frac{1}{5}}{B}$.

b may be determined from the following considerations. The edges of the plane $a1$, parallel to its intersection with $c1$, must be parallel to the diagonals of the lateral planes. The planes b therefore which cut M parallel to the intersection of $a1$ and $c1$ must intersect M parallel to a diagonal, and the symbol of the planes b must therefore be of the form A_v. But as $c3$ is cut in parallel lines by b, (300.) b must cut a *terminal* and *lateral* edge in the ratio of one to five, and its symbol must therefore be A_5. It must also cut the terminal edges in the same ratio, and hence as

$c1$ is cut in parallel lines by b, (fig. 141,) the symbol of $c\,1$ must be $\overset{\frac{1}{3}}{G}$.

$a2$ being cut parallel by the planes b, (302.) must have its index of the form $\frac{2\,p\,q}{r\,(p+q)}$. But as it has been found in the symbol representing b that

$$p = 1$$
$$q = 5$$
$$r = 5,$$

the symbol of $a\,2$ becomes $\overset{\frac{1}{3}}{A}$.

d is known to have for its symbol $\overset{1}{G}$, and the symbol of

$e\,2$ may be ascertained, by a construction analogous to fig. 139, to be $\overset{\frac{1}{3}}{G}$.

Hence all the planes of this complicated figure may be determined from the measurement of $c1$ and $c3$.

(321.) Particular cases of Parallelisms will also give the laws of particular planes, as may be seen in a Memoir by Mr. Montiero on the Law of Decrement producing a particular Crystal of carbonate of lime, inserted in No. 201 of the *Journal des Mines* for September, 1813.

Fig. 149 represents the Crystal examined by Mr. Montiero.

The planes m, m', were known by the striæ on their surface parallel to their oblique diagonal to correspond with *Mod. m* of the rhomboid.

The position of the planes m and m', relatively to the edge of the primary form, being thus known, it was readily perceived that the plane e corresponded with *Mod.* c of the same rhomboid, and the planes q with some particular modification belonging to class q.

Let fig. 150 represent the primary rhomboid of carbonate of lime. The plane m' (fig. 149) is known to result from a decrement by one row on the superior edges of that rhomboid. The lines $i\,l$, $l\,m$, would, therefore, represent the intersections of the plane m' with the primary planes, the points l and m being the middle of the edges $d\,f$ and $f\,l$.

From the middle of the edge $d\,s$, draw $h\,b$, $h\,f$, and the triangle $b\,h\,f$ will represent the position on the primary form of the plane e. (Fig. 149.)

The planes m' and e are thus observed to intersect each other at the points c and n, and, consequently, the line $c\,n$ would correspond to their edge of combination.

This edge in fig. 149 is replaced by the plane q, and from the Parallelism of its Edges it must itself be parallel to the edge it replaces.

If, therefore, the line $q\,r$ be drawn parallel to $a\,b$ and passing through the point c, and the line $o\,p$ parallel to $q\,r$ and passing through the point n, we shall, by joining $o\,q$ and $p\,r$, obtain the position on the primary form of the plane q.

And the ratio of $q\,d$ to $d\,o$, will give the Law of Decrement by which the plane q has been produced.

It is evident that $d\,h = f\,m$,

and $o\,h = p\,m$.

But $df : dh :: on : oh$,

and $fm : fl :: pm : pn$,

$\therefore\ df : fl :: on : pn$,

$:: oh : pf$,

$:: 2 : 1$,

$\therefore\ qd : do :: 3 : 1$;

therefore the plane q is produced by a decrement of three rows in breadth on the plane $a\,b\,d\,f$

On the Methods of Drawing the Figures of Crystals.

(322.) The representation of surfaces, or solid bodies, upon a plane, is the object of the art of perspective.

The theory upon which this art has been founded, supposes an imaginary transparent screen to be interposed between the eye of the observer and the object to be represented; and it supposes also that the rays of light which pass from the object to the eye become, as it were, fixed on the screen, so that when the object is removed, its figure or representation still remains. And the rules of perspective teach the methods of delineating the figures of objects upon a plane, so as to resemble the appearance they would present to the eye if the plane on which they are delineated were transparent, and held between the objects and the eye.

A more familiar conception of the nature of a perspective representation may be derived from looking at a building, or along a street, through a piece of glass, and marking lines on the surface of the glass coinciding with those we are observing through it. These lines, if accurately traced, will evidently represent the object to the eye, such as it appeared when seen through the glass.

When the object observed is a street, the upper and lower edges of the fronts of the houses, which are known to be nearly if not accurately parallel, appear to converge at the remote end of the street, forming a series of lines on the screen something like that shown in fig. 151.

And if this mass of houses were a single solid body, and even much reduced in dimensions, it ought still to be represented on a plane surface by converging lines similar to those in the above figure.

But such a representation of Crystals would convey a very indistinct idea of their forms, and particularly those of complicated secondary Crystals.

Another kind of perspective has therefore been used, which supposes parallel lines to be drawn from the several angles of the figure obliquely to a plane parallel to a lateral plane of the cube and square prism, and to a diagonal of the other forms; a method of projection in which all the lines that are parallel in the figure are represented by parallel lines in the drawing. The axis of the rhomboid, and the lateral edges of the other forms being drawn perpendicular to the plane on which the figure is supposed to rest.

(323.) *To draw a cube or square prism.* Fig. 152.

For a cube make $e\,g\,h\,f$ a square, and for a square prism make $e\,o$ or $e\,o'$ to $c\,f$ in the same proportions as they are found in the Crystal to be delineated.

Take $f\,i$ and $k\,i$ such that the figure may appear symmetrical, and draw $k\,v$, and the other lines to complete the figure.

(324.) *To draw a right rhombic prism.* Fig. 153.

On a horizontal line $a\,b$ take $a\,c = d\,b$; and from the points a, b, c, d, raise the four perpendiculars shown in the figure. Take $a\,e = b\,f$ such as to give the figure a convenient form for placing the secondary planes upon it.

Take $d\,g$ to $a\,b$ in the proportion of a *lateral* edge to the *greater* diagonal of the Crystal to be delineated, and complete the figure.

(325.) The oblique rhombic prism may be drawn in a similar manner. But as the angle $e\,d\,f$ may sometimes be acute, the ratio of $a\,b$ to $d\,g$ must be that of the *horizontal* diagonal of the Crystal to a lateral edge; and $a\,c = b\,f$ should be so taken as to present the most correct representation of the true character of the Crystal.

(326.) *To draw a doubly oblique prism.* Fig. 154.

As the lateral edges of this prism are not perpendicular to either of its diagonals, its base cannot rest on a horizontal plane, while its lateral edges are perpendicular.

On the line $a\,b$, the perpendiculars at a, c, d, and b, may be raised, and the distances $a\,c = d\,b$, and $a\,e$ and $f\,b$ may be taken so as best to represent the character of the given Crystal, the ratio of $e\,a$ to $f\,b$ and of $c\,g$ to $a\,b$ being deduced from its measured angles.

(327.) *To draw a rhomboid.*

Let $a\,b$ (fig. 155) represent the axis trisected by the parallel lines $e\,g$, $h\,k$.

From a draw $a\,g$ at such an angle with $a\,b$, and through the point f in the axis draw $e\,g$ at such an angle with the axis, as to place the figure in a convenient position for exhibiting the secondary planes.

The ratio of the axis $a\,b$ to the horizontal diagonal $c\,d$ of the rhomboid to be delineated is supposed to be known.

On the line $e\,g$ take $f\,g = 2\,f\,e$, and through e and parallel to $n\,o$ draw $e\,c = e\,d$, such that $c\,d : a\,b$ as the horizontal diagonal to the axis.

Draw $c\,e$, $d\,m$, and $h\,b$, equal and parallel to $a\,g$, and then the remaining lines to complete the figure.

(328.) The delineation of the secondary forms of Crystals may be effected either by truncating the figures of the primary forms, or by circumscribing those forms with the planes of the secondary Crystal.

When the secondary form, whether it be simple or compound, is to be exhibited in its entire state, with all the primary planes effaced, the best method will be to delineate a small primary form, and to envelope that with the secondary planes; but when parts of the primary planes are also to be shown in the figure of the secondary Crystal, a larger primary form may be drawn, and then be cut down, as in the Tables of Modifications.

The fidelity of the representation of any secondary form, will depend upon the accuracy with which the intersections of the secondary planes with the primary and with each other are drawn.

From the preceding explanations relative to secondary planes, it is obvious that such planes may be correctly placed on a primary form by drawing them so that they shall cut the primary edges in the proportions denoted by the Laws of Decrement which produce them. And the line at which two planes so drawn intersect each other, corresponds to their common edge on the Crystal.

If the planes *b* of the right rhombic prism (fig. 74) be supposed to correspond to the symbol, $(B_2\, B'_1\, H_3)$, those proportions of the corresponding edges must be taken for the plane *b*, and for *b'*, $(B_1\, B'_2\, H_3)$, and the line at which these planes would cut each other, would represent the edge between *b* and *b'*.

But it will be inconvenient when there are many secondary planes to be drawn, to find the intersections in this manner. And we must then resort to the following general method.

(329.) Let it be required to draw a right rhombic prism modified by planes corresponding to the symbols

$$\overset{2}{B},\ \overset{2}{E},\ \overset{1}{G},\ A_{\frac{1}{3}},\ (B_2\, B'_1\, H_3)$$

$$e,\quad c,\quad h,\quad b,\qquad\qquad b_2.$$

Let the primary forms (fig. 156 and 157) be drawn in pencil, of equal dimensions; with their terminal and lateral edges respectively parallel, on fig. 157 draw *u o* parallel to the short diagonal of the terminal plane, and from the points *u* and *o* draw *u o v p*, parallel to the lateral edges. The plane *h* would evidently be represented by *u v o p*. Let the line *a a'* be drawn on the plane *h*, and through the diagonals *q r*, *s t*.

The plane *c* which should next be drawn must obviously lie between *h* and P. The Law of Decrement from which this plane is supposed to result, is two rows in breadth.

If, therefore, two of the primary terminal edges of fig. 156 are extended to *c* and *c'*, so that $q\,c = 2\,q\,q''$ and $q\,c' = 2\,q\,q'$, the plane *a c c'* will represent the plane *c*, and the line *c c'* will touch the primary form at the solid angle *d*. The line *d a*, which bisects *c c'* at *d*, may be called the *directing line*, for placing the plane *c* between *h* and P, by taking some point *d* in the diagonal *q r*, (fig. 157,) and drawing *d a* parallel to *d a*. (Fig. 156.) The lines *g h'*, *i k* being drawn through *d* and *a* parallel to *u v*, the plane *g h' i k* will represent the required plane *c*. By drawing lines parallel to *g h'* and *i k*, at corresponding distances from the diagonals *q r*, *s t*, and from the points *q*, *r*, *s*, and *t*, the figure with the planes *h* and *c* upon it may be completed, and may be traced separately in pencil, as in fig. 158, preparatory to the addition of the planes *e*.

Methods of Drawing the Figures of Crystals.

To produce these planes, first draw *k x* on fig. 158, and for the intersection of the planes *c* and *e* draw *k l* parallel to *a c*, (fig. 156,) and from the point *l* draw *l y* parallel to *k x*.

Having thus produced the planes *d*, *c*, and *e*, we may add the planes b_1 and b_2, by tracing fig. 158 on a separate paper, as in fig. 160, and drawing parallel to it an entire primary form, as shown by fig. 159.

The directing planes $b\, b'''\, b_1$, and $b'\, b''\, b_1$ on fig. 159, represent the two planes b_1, b'_1, (fig. 160,) and $b\, b'''\, b_2$, $b'\, b''\, b_2$, (fig. 159,) represents b_2, or 2 in fig. 160; and $n\, z\, b'''\, z'$ (fig. 159) is evidently parallel to plane *e*, fig. 160.

The intersection of $b\, b'''\, b_1$, with $n\, z\, b'''\, z'$, is the line $n\, b'''$; its intersection with P is $b\, b'''$; with M, it is $b\, b_1$; and with $b'\, b''\, b_1$ it is $b_1 m$.

If, therefore, from the point 1 (fig. 160) we draw the line 1 6, parallel to $n\, b'''$; 6 5, to $b\, b'''$; and 1 3, to $b\, b_1$, we shall obtain three of the edges of plane b_1. From the point 5, (fig. 160,) draw the intersection of b_1 and b'_1 parallel to $m\, b_1$, (fig. 159,) and by drawing on fig. 160, 3 4, parallel to $b\, b_2$, and the intersection of 2 and 2', (fig. 160,) parallel to $m\, b_2$, (fig. 159,) we shall delineate the planes b_1 and 2; observing that those planes intersect each other in a line parallel to the intersection of b_1 and P. The positions of b'_1 and 2 may be obtained by a similar method of proceeding, and the other corresponding planes may be drawn by a similar process, or by parallel lines, or by finding the relation of their edges, or angles, to some known points on the Crystal.

By means analogous to these, the most complicated figures may be accurately produced.

(330.) But it very frequently happens that the Law of Decrement will suggest some relation between the position of the secondary edges or angles and some known points or lines of the primary form, which will supersede the necessity of any directing diagram. The figure of the rhombic dodecahedron affords an example of this nature.

The easiest method of drawing this figure is to project the cube, as shown in fig. 161, and through its centre, and perpendicular to its planes, to draw the lines *a b*, *c d*, *e f*.

Those lines are parallel respectively to the edges of the cube. Take on each line, and in each direction from the point in the centre of the cube, where the lines intersect each other, a quantity equal to that edge of the cube to which the particular line is parallel, and draw lines from the extremities of those portions of the lines to the solid angles of the cube.

Many expedients will probably occur to those who are accustomed to draw Crystals, which will greatly abridge the laborious processes just described. These will, however, form particular cases, and will depend on the degree of attention and ingenuity employed in framing the diagrams.

Introductory Observations.

(1.) **Mineralogy** is defined by Kirwan to be *the Art of distinguishing Mineral substances from each other.*

All bodies found in or upon the earth, not being vegetable or animal, are termed Minerals.

(2.) It has been stated in the Introduction to Crystallography, that we are indebted to Haüy for the first satisfactory explanation of the mutual relations of crystalline forms; and it is also due to his memory to add, that his views of Mineralogy were more precise and philosophical than those of any author by whom he had been preceded. In recommending this pursuit to the favourable notice of others, he observes, that if the motives by which we are led to the cultivation of any branch of Natural Science, were founded solely upon the pleasure afforded by a casual inspection of the productions to which it relates, Zoology and Botany would claim our first regard; but that if we overcome this first unfavourable impression, and look a little more closely to only a few individuals belonging to the Mineral kingdom, we shall, he says, find them possessed of a regularity of structure, an almost infinite variety of distinct, yet related forms, and many other properties, not only capable of affording a high degree of interest, but offering inducements to the collector of Minerals to enter upon a wider range of philosophical inquiry.

The necessity of exact Mineralogical knowledge to the Geologist has been very justly and forcibly expressed by Mr. Aikin in the introduction to his *Manual of Mineralogy*, published in 1815. He says: "The absolute necessity of extreme accuracy in discriminating one species of Mineral from another is too obvious to require any further remark, if examples were not perpetually presenting themselves of persons very slenderly provided with these rudiments of the Science, who yet undertake geological investigations, and with a peremptoriness, generally in proportion to their ignorance, challenge the credit of new discoveries, or call in question the observations of their predecessors. "It is, indeed, very true that geological speculations are as fascinating to the student as the discrimination of species is generally repulsive; yet it ought to be borne in mind that as all sound scholarship is founded upon Grammar, so all sound Geology depends primarily on a familiar acquaintance with the distinctive characters of simple Minerals."

Of Mineral Species.

(3.) If we examine specimens of the various kinds of Minerals, they will be found to differ considerably in form and colour: some will be opaque, others more or less transparent; and among those which are transparent, some may be observed to produce a double image of the objects seen through them. If the specimens are taken in the hand, some will be found much heavier than others of the same apparent size. If an attempt be made to scratch them with a pin or needle, some will be readily marked by the pin, others will require the steel point to produce the same effect; and others will not be scratched by either. Some may be cut with a knife into thin slices, while an attempt to cut others will produce only powder or fragments, and many will entirely resist the action of the knife. Some may be hammered into thin plates, while others will only be bruised to powder, or broken into angular fragments with plain or curved surfaces.

(4.) If the different specimens were to be analyzed by the Chemist, many of them would agree, and many differ in their composition, apparently denoting identity or difference *of kind* among the Minerals examined; and it might be expected that such Minerals would also be distinguished by corresponding resemblances or disagreements in their external and other characters. But it would occasionally be perceived that specimens which agreed in their chemical composition, exhibited differences in some of their external characters; and that others which agreed in their external characters, differed in their chemical composition. There would, however, *generally* be found among the external or physical characters some which so constantly accompany particular chemical kinds, as to warrant the conclusion that such characters are essential to such *kinds*: but it must be admitted that, until the relations between the chemical and other properties shall be more correctly ascertained, the separation of all the known Minerals into *kinds* or *species*, must, in many instances, be regarded as provisional only, and subject to alterations as their properties become better understood.

(5.) It appears from chemical analysis that *carbonate of lime* which occurs generally in *rhomboids*, as in the common calcareous spar, occurs also in *rhombic prisms*, as in arragonite; and hence it follows that the same elements are subject to different modes of crystalline arrangement. It is apparent that carbonate of lime and arragonite might, from the similarity of their composition, be regarded as belonging to the same *natural* species; while the differences in their form and in their physical properties, which are also *natural* characters, would require them to be considered as distinct *natural* species; but as the practical purpose for which Minerals are divided into species, that of affording the means of distinguishing them from each other, is more completely answered by regarding them as different species, they have been so considered by previous writers on Mineralogy. This property of crystallizing under two distinct forms has been termed *dimorphism;* and in order to preserve a consistent Mineralogical rule, *all* dimorphous substances ought to form two species; and even sulphur, although a *simple* chemical body, as it crystallizes under two separate forms, ought not, perhaps, to become an exception to the rule. Hence it is obvious that there might be two distinct *natural* systems of classification of Minerals, distinguished as the *Chemical* and *Mineralogical;* and if all the discrepancies between Chemical and Mineralogical species were analogous to those of carbonate of lime and arragonite, there would be little difficulty in classing and arranging the whole according to either of these methods. But there are other anomalies

in the relations of the composition and form of Minerals, arising out of what has been termed the *isomorphism* of their molecules, which tend still further to embarrass the distinction of species among several well-known substances. On this subject, however, we must refer our readers to some papers in the Xth volume of the *Phil. Mag.* and *Annals of Philosophy*, and to the *Reports of the British Association for the Advancement of Science.*

(6.) In addition to the uncertainties already noticed in the determination of Mineral species, some further difficulty may occasionally be experienced from the changes which are found to have taken place in the substance of Minerals, without any alteration of external form or cleavage. A Mineral so altered has been termed *epigene* by Haüy; and examples of such changes may be observed in iron pyrites, where the sulphur has left the iron, and oxygen has taken its place; and in carbonate of iron, where the carbonic acid has quitted the Mineral, and left it in the state of an oxide. In both these instances the crystalline forms of the pyrites and carbonate of iron are retained.

(7.) The substance of one Mineral is also occasionally found to have been destroyed or removed, and to have been replaced by that of another, which yet retains the form of the original substance, a change to which the term *pseudomorphism* has been applied. It is not unfrequent among Minerals, but its causes are involved in great obscurity.

(8.) It has also been supposed that Minerals may *pass* from one species into another. As where two distinct species are so mixed, that neither should appear to predominate or envelope the particles of the other, and to assume its proper form and other characters. But the only difficulty that could present itself in this case would arise, not from the compound exhibiting a *false* character, but from its being destitute of *any* precise specific character.

Of Classification.

(9.) Let us suppose that the physical and chemical characters of all the varieties of known Minerals have been ascertained and accurately recorded. The next proceeding of the owner of such a collection would probably be an attempt to arrange these descriptions, so as to exhibit the *natural* relations of the different kinds to each other. In attempting to effect which object, he would immediately perceive that there might be as many different systems of *natural* classification as there are distinct natural characters among Minerals. And hence his first difficulty would be the selection of the particular characters which might afford the best foundation of his *natural* arrangement; but for reasons which we have not space here to discuss, he would probably adopt the chemical composition as his basis.

(10.) Let us now imagine the supposed collection to have been destroyed, and the possessor of it to be desirous of again forming a similar one, with no other assistance than the descriptions that have been preserved of the lost specimens.

As these recorded descriptions are supposed to have been either noted down promiscuously, or to have been afterwards arranged according to composition, it is obvious that however correctly they may have been recorded, they would afford little assistance in identifying new specimens; for the time and labour that would be required for successively comparing each new specimen with each individual description of those which had been destroyed, would render the attempt impracticable.

In order, therefore, to facilitate the recognition of species from recorded descriptions, and thus to practise the *Art of Mineralogy*, it would be found necessary to classify and arrange the several characters with a view to this particular object, and thus to produce what may be termed an *artificial* arrangement.

Mineralogy may therefore be regarded both as a Science and an Art. As a Science in reference to the knowledge requisite for supplying accurate descriptions of Minerals, and forming what may be termed a *natural* classification; and an Art in reference to the arrangement of the descriptive characters for the purpose of afterwards distinguishing Minerals from each other.

(11.) Before we proceed to explain the methods which have been adapted to these purposes, we shall follow Berzelius in a hasty review of the History of Mineralogy, and the methods of classification adopted by preceding authors.

Little is to be discovered in the writings of the Ancients relative to Mineralogy in the modern sense of that term. On the contrary, the earliest histories and descriptions of Minerals are interspersed with fabulous accounts, such as Pliny has recorded of the diamond; which he says is so hard that no blow of the hammer will break it, but that when struck upon an anvil, it will rather split both the anvil and the hammer than suffer itself to be broken, unless it be previously steeped in the blood of a goat recently killed.

The first attempts at a methodical arrangement of Minerals, and the first use of the term *Mineral Kingdom* must be referred to the XVIIth Century, within which period many different systems, or Mineralogical methods, have been published. Some founded on external and physical characters only; others uniting the chemical character to these; and some later ones being strictly chemical.

Wallerius, one of the most distinguished of the early writers, arranged his *species* of Minerals by some of their external and physical characters; such as texture, fracture, figure of the fragments, colour, transparence, hardness, as evinced by giving sparks with steel, effervescence with acids, &c. The systems of Brunner and of Cronstedt were also founded on external characters, and consisted of four principal subdivisions:

Earths,	Bitumens,
Salts,	Metals.

And each of these classes was subdivided into the following orders, dependent on texture or structure.

1. Earthy,	5. Fibrous,
2. Scaly,	6. Granular foliated,
3. Foliated,	7. Compact.
4. Radiated,	

The salts being further determined by their flavour; as

Astringent,	Sweet,
Acid,	Salt, &c.

These systems, it may be observed, were founded at a period when Chemistry had made comparatively little progress; but as that Science improved, we find it resorted to by Mineralogists for supplying other distinguishing characters.

The systems of Werner and of Haussmann were founded upon the chemical and external characters conjointly; and that of Werner was for a considerable period almost exclusively adopted by Mineralogists. It was not, however, published by the author himself, and

coming only through the hands of his pupils, may possibly not have always represented his views with accuracy.

The following is an outline of his method of classification:

Class 1. Earthy Minerals.
Class 2. Saline Minerals.
Class 3. Inflammables.
Class 4. Metals.

In this system the advantages which might result to the Science from any single *natural* method, are unavailable to the student. For the chemical arrangement is continually violated to preserve an apparent consistency in that founded on external characters, which, in its turn, is not unfrequently disturbed by the regard paid to chemical constitution. And hence its followers have seldom agreed concerning the proper place which new Minerals ought to occupy in that system. The system of Haussmann was also founded upon a chemical basis, but more perfect than that of Werner, and was also combined with the consideration of external characters. And hence the disadvantage of attempting to combine conflicting and incompatible systems, was as apparent in this as it had been in the system of Werner.

The principal systems founded on a more strictly chemical basis were first those of Karsten and of Haüy, and, at a later period, of Brongniart, Cleveland, and Phillips; that of Karsten may be said to present the dawn of an attempt at accurate *natural* classification, which has been greatly improved in the hands of Haüy, and has derived still greater advantages from the labours of Berzelius. We shall, therefore, enter no further into the system of Karsten than to say, that its leading divisions are into

1. Earths, 2. Salts,

containing all the soluble varieties arranged according to their acids,

3. Combustibles, 4. Metals.

(12.) The system of Haüy was first published in 1801, and a second edition in 1822.

His definition of a Mineral species is, that all the individuals belonging to it *shall be similar in their composition*, and that their *crystalline forms shall also be similar*. It is obvious from what has preceded that this definition cannot be universally applied. If, he says, we collect crystals of quartz from different parts of the World, we shall observe such a general resemblance among them as would lead to a conclusion of their being similar Minerals. If we examine them chemically, we are supported in this conclusion; and if we measure their angles, we shall find such an agreement among the corresponding ones of different crystals as to leave no doubt that they all belong to one species. Let us now, he says, take a rolled pebble whose lustre, when broken, resembles the fractured parts of crystals of quartz. We analyze the substance, and find it nearly pure silex; we place it in a position in which we may observe the light reflected from its fractured surface, and we perceive that from some parts of that surface not only the rays of light, but the images of objects, are distinctly reflected; we consider those parts as portions of cleavage planes, we detach and measure some fragments, and we discover angles corresponding with some of those presented by the regular crystals of quartz; we therefore include our specimen under the species quartz. We proceed with another specimen of what is termed white cornelian, whose structure is fibrous, whose fragments afford but dull reflections of light, and not any images of surrounding objects. This differs so much in character from the preceding specimens, that at first view we should exclude it from the species. But on analysis, we find that its composition is very nearly similar to that of rock crystals; and as an analogy has been observed to subsist between the crystallized and fibrous structure of other Minerals, we place our white cornelian as a variety of the species quartz.

The following is an outline of the classification adopted by Haüy:

Class 1. Free acids.
Class 2. Metals appearing under another character. (Heteropsides.) These are the earthy Minerals.
Appendix to class 2. The characteristic principle depending upon the silex not yet determined, and being free or combined.
Class 3. Metals appearing as such. (Autopsides.)
Order 1. Not immediately oxidable, unless at a very high temperature, and immediately reducible.
Order 2. Oxidable, and reducible immediately.
Order 3. Oxidable, but not immediately reducible.
a. Sensibly ductile.
b. Not ductile.
Class 4. Combustibles, not metallic.
An appendix to this class, consisting of substances of vegetable origin.
Appendix to the four preceding Classes.
22 substances.

This classification appears equally objectionable with those preceding it, exhibiting as it does a mixture of chemical and physical characters in the same system.

We pass over the systems of Brongniart, Cleveland, Phillips, Breithaupt, Beudant, and other authors who have intervened between the first publication of Haüy's method and the present time, not as unworthy of more particular notice, but because they may be regarded as varieties of the chemical method, modified in a greater or less degree by the introduction of some other principle.

We are indebted to Berzelius for the first attempt at a strictly chemical classification of Minerals. According to this author's system, all chemical compounds are supposed to consist of electro-positive and electro-negative particles, attracted and held together by a force analogous to that by which bodies in different states of electricity are influenced. When Minerals are analyzed, therefore, and their simple constituent parts ascertained, we are, according to this theory, to regard those of the electro-positive and electro-negative elements which present themselves in *such definite proportions as are consistent with the atomic theory, to be essential elementary parts of the Mineral examined*; and upon this principle a general determination of Mineral species has been attempted, and a systematic classification founded.

But this author has candidly acknowledged the difficulties which, in the present state of Chemical Science, attend the inquiry into what are really the essential constituents of Minerals. The first is that of ascertaining correctly, by means of analysis, the nature of all the different kinds of particles which enter into the composition of a compound Mineral, and the still greater difficulty of determining the exact proportions of each kind. This, however, may possibly be overcome by further improvements in practical Chemistry. But the second, and as

it appears to us the insurmountable impediment to the establishment of an accurate chemical determination of Mineral species, arises from the extraneous matter which is so frequently, we might almost say universally, found accompanying the *essential constituents* of the Mineral.

The substance known by the name of Fountainbleau sandstone affords a striking instance of this kind of composition. This Mineral may be regarded either as granular quartz cemented by carbonate of lime, or as carbonate of lime enveloping grains of quartz, yet no one has ever regarded this mixture as constituting a new chemical species. Instances also occur in which only part of a specimen is coloured by foreign matter, which, if it had pervaded the whole specimen, the Chemist would be deceived by analysis, and would erect an accidental variety of some known Mineral into a new species.

On looking over the number of species which Berzelius has formed out of the garnet tribes, it is much to be suspected that accidental mixtures have been reckoned among the essential constituents of several of the varieties examined; a suspicion which may be reasonably entertained from the manner in which the chemical formulæ of Minerals is made up. For we can scarcely imagine a compound, however heterogeneous, whose constituent particles may not be so parcelled out as to appear nearly definitely proportional to each other. It is, however, very possible that some of the Minerals hitherto called garnets, on account of their crystalline form, may really be different substances. But the number of Mineral species which may fairly be regarded as doubtful on account of some supposed heterogeneous mixture of elements will probably be continually reduced by new and more correct analyses; with a due regard to the matrix, to the accompanying substances, and to the purity of the specimens analyzed, as far as that can be judged of from their transparency and other characters.

The order established by the *electro-chemical* relation of bodies is supposed to be generally preserved in all their combinations. Thus if A be *electro-negative* in respect of B and of C, B will generally be electro-negative in relation to C; but this appears not to be universally so; and sometimes one electro-negative body is found combined with two or more bases, and sometimes two acids are combined with a single base.

If, says Berzelius, with these theoretic notions in our mind we look through the productions of the Mineral kingdom, the apparently confused combinations which Minerals present will be immediately pervaded by regularity and order. We perceive an extensive class of Minerals into which silex enters as a constituent, assuming the character of salts, either simple, double, triple, or quadruple, and with various excesses of the *acid* or the *base*. In the same manner we perceive the oxides of titanium, of tellurium, and of other metals, performing the functions of acids, and thus reducing the whole series of Minerals to one uniform system of classification; and the doctrine of definite proportions introduced within a few years into Chemistry, might, if we could fully avail ourselves of its aid, be said to confer on this system of Mineralogical classification a degree of almost mathematical precision. But, as we have already stated, in consequence of the difficulty of ascertaining the proportions of the actual ingredients of Minerals, and the still greater difficulty of distinguishing those which are essential to the species analyzed, we are not yet enabled to confer on a chemical classification all the advantages offered by the improved doctrines of Chemistry.

In the large class of Minerals containing silex, and which are the only ones that are likely to occasion much difficulty, we are persuaded that there are not at present sufficient data to determine their chemical species with accuracy. And in this opinion we have the concurrence of the author himself; for he allows in his *Nouveau Système Minéralogique*, at p. 22, that although the number of analyses already made by Klaproth, and others since his time, supply a large store of materials for the determination of species, yet the entire accomplishment of this object must be the result of future labours, directed sedulously and entirely to the accuracy of analysis. And in p. 92 of the same Work he says, "I cannot be certain that the analysis of the triple or quadruple silicates, or consequently the formulæ deduced from these, are correct. I give them only as examples of the *probable composition* of these Minerals. The art of analysis not being yet advanced to that degree of perfection, which will command our reliance on its results when the ingredients of the substance analyzed are numerous." It is on these grounds that we have omitted the Mineralogical formulæ of Berzelius in this Treatise.

We have, however, adopted provisionally his chemical classification, as it appears in the *Annals of Philosophy, New Series*, vol. xi. p. 422, being, we believe, the best natural arrangement yet proposed. To the list there given, the later examined Minerals have been added.

In this arrangement we have numbered the species, and in the alphabetical list we have given references to these numbers, by which the chemical order of the different species in that list may be readily ascertained.

We have also for the more convenient reference to cabinets which may be arranged according to this system, retained the different substances in the order there adopted by Berzelius, although in his recent Work on Chemistry that order has been a little varied.

Chemical Classification of Minerals.

Iron, native, meteoric. *Aerolite*, 1.
terrestrial, 1. from France, 2.
... 2. from North America, Connecticut, 3.
... 3. Pennsylvania, 4.
volcanic, 5.
native steel? terrestrial, 6.
volcanic, 7.
Copper, native, 8.
Bismuth, native, 9.
Lead, native, 10.
Silver, native, 11.
Mercury, native, 12.
Hydrarguret of silver. *Amalgam*, 13.
Palladium, native, 14.
Platina, native, 15.
Osmium.
Osmiuret of *iridium*, 16.
Gold, native, 17.
Aururet of silver. *Electrum*, 18
Tellurium, native, 19.
Telluret of bismuth, 20.
... ... and silver, 21.
... lead and silver. *Foliated?* 22.
... .. and gold. *Yellow*, 23.
... silver and gold. *Graphic*, 24.
Antimony, native, 25.
Stibiuret of silver. *Antimonial silver*, 26.

Arsenic, native, 27.
Arseniuret of nickel. *Copper-nickel*, 28.
... cobalt. *White cobalt*, 29.
hard, 30.
radiated, 31.
rhombic, 32.
... ... bismuth, iron, &c. *cobalto-bismuthic arsenic*, 33.
... bismuth, 34.
... copper, 35.
... silver. *Arsenical silver?* 36.
... antimony from *Allemont?* 37.
... . *Przbram*, 38.
... manganese, 39.
Carbon, native. *Diamond*, 40.
Anthracite, 41.
Carburet of iron. *Graphite*, 42.
Siderographite? 43.
Azote, native, gaseous, 44.
Selenium, native, 45.
Seleniuret of bismuth and tellurium, 46.
... lead, 47.
... ... and cobalt, 48.
... . copper, 49.
cupriferous seleniuret of lead, 50.
... . mercury, 51.
... .. copper and silver, 52.
... copper, 53.
... ... and silver. *Eukairite*, 54.
... zinc, with sulphur and mercury.
... ... *Riolite*, 55.
... ... *Culebrite*, 56.
Iodine. Iodide of silver, 57.
Chlorine, 58.
Chloride of sodium, 59.
... ammonium, 60.
... calcium, 61.
... magnesium, 62.
... lead, 63.
chloro-oxide. *Berzelite*, 64.
chloro-carbonate, 65.
... copper, 66.
... silver, 67.
... mercury, 68.
Sulphur, native, 69.
Sulphuret of manganese, 70.
... zinc. *Blende*, 71.

Vargasite, 379.
Wærthite, 380.
Withamite, 381.
Wolkonskoit, 382.
Xanthite, 383.
Xantholite, 384.
Zurlite, 385.

Oxide of titanium, (titanic acid.) *Anatase*, 386.
Rutile, 387.
Brookite? 388.
Titaniate of iron. *Iron sand*, 389.
Nigrine, 390.
Axotomous iron, 391
Crichtonite, 392.
Mohsite, 393.
Silico-titaniate of lime. *Sphene*, 394.
Titaniates with several bases of cerium yttria, zirconia, &c.
Pyrochlore, 395.
Polymignite, 396.
Æschynite, 397.

Tantalic acid.
Tantalates of yttria, cerium, iron, &c, *Fergusonite*, 398.
Yttrotantalite, *black*, 399.
brown, 400.
yellow, 401.
Tantalite, 402.
a. from Kimito, 403.
b. .. Finbo, 404.
c. .. Brodbo, 405.
d. .. Bavaria, 406.
e. .. North America, 407.
f. .. Kimito, *giving a cinnamon-coloured powder*, 408.
Oxide of antimony. White antimony, 409.
Oxi-sulphuret of antimony. Red antimony, 410.
Tinder ore? 411.
Scheelic acid, 412.
Scheelate of lime. *Tungsten*, 413.
... iron and manganese. *Wolfram*, 414.
... lead, 415.
Molybdic acid, 416.
Molybdate of lead, 417.
Pamplonite? 418.
Oxide of chrome, native, 419.
Chromate of iron, 420.
... lead, 421.
... lead and copper, *Vauquelinite*, 422.
Boracic acid, hydrous, native, 423.
Borate of soda. *Tincal*, 424.
... magnesia. *Boracite*, 425.
Boro-silicate of lime. *Dalholite*, 426.
Humboldtite. 427.
Botryolite, 428.
... alumina, lime, &c.
Tourmaline, 429.
a with base of potash.
b ... lithia.
c ... magnesia.
Axinite, 430.
Carbonic acid, gaseous, native, 431.
Carbonate of soda. *Oblique rhombic prisms*, 432.
right rhombic prisms, 433.
Trona, 434.
bi-carbonate? 435.
.. ... and lime. *Gay Lussite*, 436.
Barruelite, 437.
... barytes, 438.
... strontia, 439.
barytiferous. *Stromnite*, 440.
... lime, *a. Calcite*, 441.
b. Arragonite, 442.

Murindo, 584.
Asphaltum, 585.
Bituminous coal, 586.
Native Naphthaline, 587.
Schererite, 588.
Xylocryptite, 589
Mellite, 590.
Oxalate of iron, 591.

(14.) It will readily be discovered by the reader, on looking through the preceding chemical classification, that if he desires to ascertain whether a particular Mineral which he sees for the first time is included in it, the order in which the species are there placed, even supposing them accompanied by their descriptions, does not enable him to do so. Some other arrangement, therefore, which for the sake of distinction we have termed artificial, is required for this purpose.

The first attempt at an arrangement of Minerals, with a view of affording the means of recognising them, is, we believe, contained in Aikin's *Manual of Mineralogy*, and is founded on the effects produced by the blowpipe, combined with some other characters. But serviceable as this arrangement might be, it is probable from the infrequency with which the blowpipe is used by Mineralogists, that it has not afforded the assistance it is capable of rendering.

(15.) The only other attempt at an artificial arrangement of Minerals, founded on their external and physical characters, for the purposes of identifying and distinguishing them, which has been published in this Country, is the system of Mohs; that of Weiss, by which it is said to have been preceded, not having to our knowledge been printed either here or in France. The system established by Mohs, although imperfect in respect to a particular class of crystalline forms, and defective in respect to the arrangement of many of the species, which are thrown into appendices to the several *orders* of the system, is said to have fulfilled in a very great degree the object for which it was framed, and to have enabled his pupils to determine Mineral species when first presented to them with a considerable degree of precision. The translation which has appeared in this Country, although made by a pupil of Mohs, eminently acquainted with his subject, and writing our language with great correctness, is yet not given in so perfect an English dress as to enable the reader at all times to comprehend fully the meaning of the author. The difficulty, however, which the reader might experience from this cause, is nothing in comparison with that which he has to encounter in the minute analysis of the principles of the system, its learned yet repulsive nomenclature, and the symbols which represent the crystalline forms. Indeed, so formidable have these characters of the Work appeared to Mineralogists in this Country, that we believe it has had very few, if any readers. We, however, give the following abstract of the system, stripped of its repulsive appendages.

System of Mohs.

Class 1. Sp.gr. under 3.8.
No bituminous odour.
Order 1. Sp.gr. 0.0001, 0.0014.
Gaseous.
Not acid.
2. Sp.gr. 1.0.
Liquid.
No odour or taste.
3. Sp.gr. 0.0015, 3.7.
Acid.
4. Sp.gr. 1.2, 2.9.
Solid.
Soluble in water.
Not acid.
Class 2. Sp.gr. above 1.8.
Tasteless.
Order 1. Non-metallic.
Streak uncoloured.
Hard. 1.5, 5.0.
Sp.gr. 2.2, 3.3.
a. Square or rhombic prisms; Hard. 4.0 or less; cleavage imperfect, oblique.
b. Cube; Hard. 4.0.
c. Single cleavage, bright; sp.gr. 2.4 or less.
d. Hard. under 2.5; sp.gr. 2.4 or less.
e. Hard. under 2.5; sp.gr. 2.4 or less; lustre not resinous.
2. Non-metallic.
Streak uncoloured, or orange yellow
Hard. 2.5, 5.0.
Sp.gr. 3.3, 7.3.
a. Single cleavage; sp.gr. 4.0 or less, 5.0 and more.
b. Lustre adamantine or imperfect metallic; sp.gr. 5.0 and more.
c. Streak orange-yellow; sp.gr. 6.0 and more.
d. Hard. 5.0; sp gr. under 4.5.
e. Hard. 5.0; sp.gr. under 4.0; triple cleavage.
3. Non-metallic.
Streak uncoloured.
Cleavage not single, imperfect.
Hard. 1.0, 2.0.
Sp.gr. above 5.5.
4. Non-metallic.
Colour blue, green, brown.
Cleavage not single.
Hard. 2.0, 5.0.
Sp.gr. 2.0, 4.6.
a. Colour or streak brown; Hard. 3.0 or less; sp.gr. above 2.5.
b. Streak blue; Hard. 4.0 or less.
c. Streak uncoloured; Hard. under 3.0; sp gr. 2.2 or less.
5. Cleavage single, bright.
Hard. 1.0, 4.5.
Sp.gr. 1.8, 3.2.
a. Metallic; sp.gr. under 2.2.
b. Non-metallic; sp.gr. above 2.2.
c. Rhomboid; Hard. 3.0 and more.
d. Metallic; sp.gr. under 2.5.
6. Non-metallic.
Streak uncoloured, brown, blue.
Hard. 3.5, 7.0.

Class 2. *continued.*
Order 6. *continued.*
Sp.gr. 2.0, 3.7.
a. Cube; sp.gr. 3.0 or less.
b. Rhomboid; Hard. 6.0; sp.gr. 2.2 or less.
c. Single cleavage, bright; Hard. 4.0 or less.
d. Lustre pearly; Hard. above 6.0; sp.gr. under 2.5, or above 2.8.
e. Lustre not adamantine; oblique rhombic, or doubly oblique prisms; Hard. 6.0; sp.gr. above 3.3.
f. Traces of form and cleavage; sp.gr. 2 4 or less.
7. Non-metallic.
No metallic adamantine lustre.
Streak uncoloured.
Hard. 5.5, 10.0.
Sp gr. 1.9, 4.7.
a. Hard. 6.0, or less.
Cube; sp.gr. 3.0 and more.
No form or cleavage; sp gr. 2.4 or less
b. No pearly lustre, on cleavage planes; sp.gr. under 3.8.
8. No green streak.
Hard. 2.5, 7.0.
Sp.gr. 3.4, 7.4.
a. Metallic; colour black.
b. Non-metallic; lustre adamantine or imperfect metallic.
c. Streak yellow or red; Hard. 3.5 and more; sp.gr. 4.8 and more.
d. Streak brown or black; Hard. 5.0 and more; or single cleavage.
e. Streak yellow, red, or black; Hard. 4.5 or less.
f. Streak uncoloured; Hard. 6.5 and more; sp.gr. 6.5 and more.
9. Metallic.
Colour not black.
Hard. 0.0, 5.0.
Sp.gr. 5.7, 20.0.
a. Malleable; colour grey; sp.gr. 7.4 and more.
b. Malleable; Hard. above 4.0.
10. Metallic.
Hard. 3.0, 6.5.
Sp gr. 4.1, 7.7.
a. Hard. 4.5 or less; sp.gr. under 5.3.
b. Colour yellow or red; sp.gr. 5.3 or less.
11. Metallic.
Colour grey, black.
Hard. 1.0, 4.0.
Sp.gr. 4.2, 7.6.
a. Colour lead-grey; single cleavage; sp.gr. under 5.0.
b. Colour lead-grey; sp gr. above 7.4.
12. Streak green, brown, red, uncoloured.
Hard. 1.0, 4.0
Sp.gr. 3.9, 8.2.
a. Metallic; colour black.
b. Non-metallic; lustre adamantine.
c. Streak green; colour black.
d. Streak brown, uncoloured; cube; sp.gr 4.0, 4.2.
e. Streak red; Hard. 2.5 or less.
f. Streak red; sp.gr. 4.3 and more.

Class 2. *continued.*

Order 13. Non-metallic.
Colour yellow, red, brown.
Rhombic prism.
Hard. 1.0, 2.5.
Sp.gr. 1.9, 3.6.
a. Single cleavage; sp.gr. 3.4 and more.
b. Streak yellow, red; sp.gr. above 2.1.

Class 3. Sp.gr. under 1.8.
a. Fluid; bituminous odour.
b. Solid; tasteless.

Order 1. Hard. 0.0, 2.5.
Sp.gr. 0.7, 1 6.
a. Streak uncoloured. sp.gr. 1.2 and more.

2. Streak brown, black.
Hard. 1.0, 2.5.
Sp. gr. 1 2, 1.5.

We recommend the reader, if he wishes to ascertain the real value of this arrangement, to attempt a classification of the Minerals he is acquainted with by the characters here given, and to compare his result with the order in which the several Minerals are placed in the translation we have referred to.

(16.) The very brief descriptions given in the following list are all that the space allotted to this Essay will allow, and we must refer the reader to Leonhard's *Handbuch der Oryctognosie*, for the results of Chemical analysis; to Haüy's *Traité de Minéralogie*, and to Phillips's *Elementary Introduction*, for figures and measurements of Crystals; and to the "observations" in Haidinger's translation of the system of Mohs, for much valuable Mineralogical information.

The alphabetical form we have given to our list, will be found convenient for reference. Although, however, the leading form of our list is alphabetical, it is also, with the exception of the compound silicates, chemically arranged according to the *bases*, by which order the ores of each metal are kept together. The reader has thus the two chemical classifications before him. That already given from Berzelius being arranged according to the *acids* with a particular view to the theory of isomorphism.

We have deemed it advisable to give single names to some of the species that before had only their chemical designation, as *Calcite* to Carbonate of lime. These names have generally been derived from places or persons, having observed that significant names derived from some property or character or theoretical view of the substances to which they have been applied, have frequently led to the mistakes of one substance for another, merely because the property from which the significant name was derived, happened to be common to both.

We observe, in looking at the late editions of Beudant's *Mineralogy* and Breithaupt's *Carakteristik*, that these authors also have felt the advantage of denoting Minerals by single names; but they have carried their alterations very much further than appears to be necessary, and they have too frequently followed the exceptionable examples before them, of employing a significant nomenclature.

We have deemed it sufficient to refer specially to the Works of Haüy, Phillips, Haidinger, and Leonhard, as the reader will find in these ample references to other authorities. But we have occasionally found it necessary to quote from other books.

The abbreviations used are the following.

Haüy. *Traité de Minéralogie*, second edition, 1822.

Phil. *Elementary Introduction to Mineralogy*, by W. Phillips, 1823.

Haid. *Treatise on Mineralogy*, by F. Mohs, translated by W. Haidinger, 1824.

Leon. *Handbuch der Oryctognosie*, by K. C. v. Leonhard, 1826.

B.M. *British Mineralogy*. by J. Sowerby.

N.J. Nicholson's *Journal*, 8vo.

P.M. *Philosophical Magazine.*

S.J. Silliman's *Journal.*

An. *Annals of Philosophy.*

An. N.S. *Annals of Philosophy, New Series.*

P.M. and An. *Philosophical Magazine and Annals.*

P.M. and J.S. *Philosophical Magazine and Journal of Science.*

E.P.J. *Edinburgh Philosophical Journal.*

E.P.J. N.S *Edinburgh Philosophical Journal, New Series.*

E.J.S. *Edinburgh Journal of Science.*

E.J.S. N.S. *Edinburgh Journal of Science, New Series.*

Q J.S. *Quarterly Journal of Science.*

Lucas. *Tableau des Espèces Minérales*, 1813.

Gal. *Recueil Minéralogiques par le* Prince Dimitri de Gallizin.

The Mineralogical student will find much useful matter in the Treatises on Mineralogy by Kirwan, Jameson, Aikin, Cleaveland, and those of later writers in France and Germany.

We have followed Mohs in the numbers which express the degree of hardness (Hard.) of Minerals, his scale being as follows.

1. Green talc.	6. Adularia.
2. Gypsum. Rock salt.	7. Quartz.
3. Carbonate of lime.	8. Topaz.
4. Fluorspar.	9. Corundum.
5. Apatite.	10. Diamond.

But we are persuaded that this character requires to be much more accurately ascertained than it has hitherto been, and by a more strict method of comparison than merely passing a knife or file over the substance, and estimating its hardness by the degree of resistance it appears to offer.

Alphabetical List of Minerals.

ACHMITE. *Euchysiderite.* No. 267.
Haid. 3.67. Leon. 513.
Has the form, cleavage, and measurement of Pyroxene. Hard. 6.0, 6.5. Sp.gr. 3.24. Nearly opaque. Lustre vitreous. Colour brownish-black. Streak yellowish-grey.
Found at Eger in Norway.

ALUMINA.

Fluate of Alumina.

a. FLUELLITE. No. 513.
Sowerby, *Brit. Min.* 3.83. 1807. An. 8.242. Haid. 3. 101. Leon. 739.
Occurs in attached octahedral crystals.
Primary form, a Right rhombic prism. CRYST. fig. 71. M,M′=105°. Transparent Colour white.
Found at Stenna Gwyn, Cornwall.

Hydrate of Alumina.

a. DIASPORE. No. 153.
Haüy, 2.163. Phil. 78. Haid. 3.92. Leon. 228.
Occurs in amorphous masses, with a thin columnar structure, the crystals crossing in every direction.

Mineralogy

Primary form, according to Phillips, a Doubly oblique prism CRYST fig 95. P,M = 108° 30′. P,T = 101° 20′. M,T = 64° 54′. Sp.gr. 3.43. Slightly translucent. Lustre vitreous. Colour slightly greenish-grey, and yellowish-brown.

Locality unknown, but supposed to have come from the Uralian mountains.

b. GIBBSITE. No. 152.

Phil. 79. Haid. 3. 103. Leon. 740.

Occurs in irregular stalactitical and tuberculated masses. Structure fibrous, radiating. Hard. 3.0, 3 5. Sp gr. 2.4. Slightly translucent. Nearly dull. Colour greenish or greyish-white. Streak white.

Found at Richmond, Massachusetts, North America.

c. CALAITE *Agaphite. Johnite.* *Mineral Turquoise.* No. 500.

Haüy, 4.516. Phil. 79. Haid. 3.83. Leon. 135.

Occurs in reniform nodules and amorphous masses, and in thin veins. Structure compact. Fracture conchoidal. Hard. 6.0. Sp gr. 2.8, 3.2. Opaque. Colour sky-blue and bluish-green Streak white.

Found in alluvial clay and in trap rock in Khorasan in Persia.

Mellate of Alumina.

a. MELLITE. *Honey stone.* No. 590.

Haüy, 4.445. Phil. 374. Haid 3.56. Leon. 790.

Occurs in attached and imbedded crystals, and small imbedded nodules or grains.

Primary form a Square prism. CRYST. fig. 65. Cleavage very indistinct parallel to the planes *a*, fig 66. Fracture conchoidal. Hard. 2.0, 2 5. Sp.gr. 1.597. Transparent, translucent. Lustre vitreo-resinous. Colour honey-yellow, sometimes reddish or brownish. Streak white.

Found attached to and imbedded in bituminous wood, principally at Artern in Thuringia.

Native Alumina.

a. CORUNDUM.

The blue transparent varieties are the Sapphire; the red, oriental Ruby; the purple, oriental Amethyst; the yellow, oriental Topaz; the opaque, adamantine spar; the granular, Emery. No. 145.

Haüy, 2. 70. Phil. 71. Haid. 2. 199. Leon. 535. 538.

Occurs in imbedded crystals and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′= 86° 4′. Cleavage parallel to P, and perpendicular to the axis. Fracture uneven. Hard. 9 0. Sp.gr. 3.91, 3.98. Transparent, translucent, opaque. Lustre vitreous. Colour white, grey, blue, green, yellow, red, brown. Streak white.

Massive varieties, amorphous. Structure perfectly crystalline, or granular and compact with a splintery fracture.

Found in India, China, North America, in Europe chiefly at St. Gothard and in Piedmont.

Alumina, with silica and carbon.

a. ROTTEN STONE. No. 146.

Phil. 50.

Occurs massive. Fracture uneven. Soft, fine earthy, soils the fingers. Opaque. Dull. Colour greyish, reddish, and blackish-brown. Fetid when rubbed or scraped.

Found near Bakewell in Derbyshire, and at Albany near New York.

Phosphate of Alumina.

a. WAVELLITE. *Lasionite.* No. 497

Haüy, 2.161. Phil. 146. Haid. 3.169. Leon. 133.

Mineralogy

Occurs in globular concretions, formed of slender crystals radiating from the centre of the globules, with imperfect terminations, producing a drusy surface. Primary form of the crystals a Right rhombic prism. CRYST. fig. 71. M,M′= 122° 15′. Cleavage parallel to the lateral planes, and the greater diagonal of the prism. Hard. 3.5, 4.0. Sp gr. 2.3, 2 7. Translucent. Lustre vitreous, sometimes pearly on the cleavage planes. Colour nearly white, grey, brown, yellow, green, of various shades.

Found near Barnstaple, in Devonshire; very rarely near St. Anstle, Cornwall; in Ireland, Germany, and Brazil.

Phosphate of Alumina and Ammonia.

a. MAURITCITE. No. 498.

An. de Ch 21.188. Leon. 783.

A white earthy substance from the Isle of France, differing from the preceding Phosphate in the proportions of its constituent parts.

Silicate of Alumina.

a. KYANITE *Cyanite. Disthene. Rhætizite.* No. 181.

Haüy, 2. 357. Phil. 81. Haid. 2. 213. Leon. 406.

Occurs in columnar imbedded crystals and massive.

Primary form a Doubly oblique prism, P,M = 93° 15′. P,T = 100° 50′. M,T = 106° 15′. Cleavage parallel to T very distinct; less so parallel to M; parallel to P indistinct. Fracture uneven. Hard. 5.0 on plane T, 7.0 on the edges and solid angles. Sp.gr. 3.6, 3 675. Transparent, translucent. Lustre vitreous, pearly on T. Colour white, bluish-grey, blue, pale bluish-green, yellow. Streak white.

Massive varieties. Aggregation of crystals promiscuously intersecting each other, sometimes very long, and occasionally so short and small as to appear large granular.

Found at St. Gothard in large crystals, in Scotland, and many other parts of Europe, and in North and South America.

b. SILLIMANITE, No. 182.

Haid. 3.153. Leon. 409

Occurs in imbedded columnar rhombic prisms, of about 106° 30′. Haid.

Cleavage parallel to the long diagonal. Fracture splintery. Hard. 8.0, 8.5. Sp.gr. 3.41. Nearly opaque. Lustre on the cleavage plane nearly adamantine. Colour dark brownish-grey.

Found at Saybrook, Connecticut, North America. It approaches very nearly to Kyanite in its form and composition.

c. BUCHOLZITE, No 183.

Phil. 109. Leon. 409.

A fibrous substance from the Tyrol analyzed by Brandes. It is described as amorphous. Cross fracture imperfectly conchoidal. Hard. about 6 0. Slightly translucent. Lustre resinous. Colour yellowish and greyish-white.

One or two other fibrous Minerals apparently different from this have passed under this name. The composition of the substance analyzed by Brandes is nearly the same as that of Kyanite, and it may have been a fibrous variety of that Mineral.

d. FIBROLITE, No. 184.

Phil. 80. Haid. 399. Leon.

Occurs in small fibrous masses. Hard. 7.5. Sp.gr. 3.214. Translucent, colour greyish-white.

Found in India and China accompanying Corundum.

Fibrous varieties of Epidote, Kyanite, and other substances have passed under this name, and the composition of Bournon's Fibrolite is very nearly the same as that of Kyanite.

e. ANDALUSITE, No. 185.
Haüy, 4.486. Phil. 108. Haid. 2.293. Leon. 404.
Primary form a Right rhombic prism. M,M′ = 90° 40′, measured on a transparent variety from North America. Cleavage parallel MM′. Fracture uneven, conchoidal. Hard. 7.5. Sp.gr. 3.104. Transparent to opaque. Lustre vitreous. Colour flesh-red to brownish and greyish-red.
Found generally in mica slate in Spain, France, and other parts of Europe, and lately in North America, in partially transparent crystals imbedded in quartz.

Hydrous silicates of alumina. A very uncertain series, several of which are, probably, only accidental mixtures in variable and indefinite proportions.

a. PHOLARITE, No. 187.
E J S. 6.364. Leon. 767.
Occurs in small, convex, nacreous scales.
Soft, friable. Colour white. Adheres to the tongue.
Found in the coal formations of Fins, Department Allier, France.

b. ALLOPHANE, No. 188.
Phil. 88. Haid. 3.69. Leon. 183.
Occurs in globular, reniform, and botryoidal masses. No cleavage. Fracture conchoidal. Hard. nearly 3.0. Sp gr. 1.85. Transparent, translucent. Lustre vitreous. Colour blue, green, brown, of several shades.
Found in limestone in Thuringia, at Schneeberg in Saxony, and probably in Derbyshire.
Some specimens, received in this Country under the name of Allophane, may be cleaved parallel to the planes of a rectangular solid, and are probably another Mineral.

c. LENZINITE. *Wallerite*, No. 189.
Phil. 87. Leon. 179.
Occurs in compact and earthy masses of various sizes.
Compact. Fracture conchoidal. Hard. 1.5. Sp.gr. 2.10. Transparent on the edges. Nearly dull. Colour yellowish milk-white. Streak shining. Feels rather greasy. In water it separates with noise into small fragments.
Earthy. Fracture earthy. Soft. Sp gr. 1.80. Slightly translucent, opaque. Dull. Colour snow-white. Streak shining.
Found at Kall in Eifeld.

d. HALLOYSITE, No. 190.
E.J.S. 6. 183.
Occurs in nodular masses. Structure compact. Fracture conchoidal. Nearly opaque. Lustre waxy. Colour bluish and greyish-white. Streak shining. Adheres to the tongue.
Found in the neighbourhood of Liege and Namur.
The analysis of this substance corresponds so nearly with that of Lenzinite as to leave little doubt of its being the same Mineral, but of a different colour.

e. SEVERITE, No. 191.
Phil. 87.
Occurs in small masses, nearly resembling Lithomarge. Fracture uneven. Hard. 1.0, 1 5. Slightly translucent. Dull. Colour white. Streak shining.
Found near St. Sever in France.

f FULLER'S EARTH, No. 192.
Phil. 52. Haid. 3.182.
Occurs massive in beds of considerable thickness. Fracture uneven, earthy. Soft. Sp.gr. 1.8, 2.2. Opaque. Dull. Colour greenish-brown, dull greywhite. Streak shining. Feels greasy.
Found in England, principally at Nutfield in Surrey, and in Stiria, Saxony, and some other places in Europe.

g. CIMOLITE, No. 193.
Phil. 54. Leon. 729.
Occurs in amorphous earthy masses, structure rather slaty. Fracture uneven, earthy. Soft. Sp gr. 2.0. Opaque. Colour greyish-white.
Found in the Island of Cimola, near Argenteria.
Used for the same purposes to which Fuller's earth is applied.

h. AGALMATOLITE. *Bildstein. Lardite. Pagodite.* No. 194.
Phil. 119. Haid. 3.100. Leon. 188.
Occurs massive. Fracture coarse, splintery. Soft. Sp.gr. 2.8. Slightly translucent. Colour white to brown, rather pale and dull. Streak shining. Unctuous to the touch.
Found in China, Transylvania, Saxony, and in Wales.
Cut into various figures by the Chinese, and seldom brought to this Country in any other state.

i. LITHOMARGE. *Steinmark*, No. 195.
Haüy, 4.558. Phil. 52. Haid. 3.183. Leon. 186.
Occurs massive. Spheroidal. Structure compact. Fracture large, conchoidal. Soft. Sp.gr. 2.2, 2.5. Opaque. Dull. Colour white, grey, red, yellow, blue. Streak shining. Adheres to the tongue. Unctuous to the touch.
Found in Saxony, and some other parts of Europe.
A *friable* variety is found at Ehrenfriedendorf in Saxony.

k BOLE, No. 196.
Phil. 53. Haid. 3.179. Leon. 191.
Occurs massive. Structure compact. Fracture conchoidal. Soft. Sp gr. 1.4, 2.0. Nearly opaque. Nearly dull. Colour brownish-black, red, yellow. Streak shining. Feels greasy. Adheres to the tongue.
Found in many places in trap rocks.
Several very different substances appear to have passed under this name, and it is doubtful if any one of them is correctly represented by the preceding description, yet we give it upon the authorites quoted.

l. MOUNTAIN SOAP, No. 197.
Phil. 53. Haid. 3.184. Leon. 192.
Occurs massive. Structure compact. Fracture fine earthy. Sectile. Opaque. Dull. Colour light brownish-black. Streak shining.
Found at Olkner in Poland.

m. LEMNIAN EARTH. *Terra sigillata*, No. 198.
Phil. 54. Leon. 191.
Occurs massive in the Isle of Lemnos. Fracture earthy. Soft. Opaque. Dull. Colour dull yellowish-grey and greyish-white.
An uncertain species.

n. KOLLYRITE, No. 199.
Phil. 88. Leon. 752.
Occurs massive, appearing like a tenacious white clay. When dry it splits into columnar masses like starch.
Found at Weissenfels in Thuringia.
The siliciferous Hydrate of Alumina, found in the

Pyrenees and analyzed by Berthier, probably belongs to this species.

o. SCARBRÖITE, No. 203.
P.M. and An. 5. 178.
Occurs as veins in the beds of sandstone covering the calcareous rock at Scarborough.
Fracture conchoidal. Hard. about 2.0. Sp.gr. about 1.48. Opaque. Dull. Colour white. Streak shining. Adheres to the tongue. Strong earthy smell when breathed upon. Does not become translucent, nor fall to pieces in water.

p. KAOLIN. *Porcelain Clay*, No. 201.
Phil. 51. Leon. 185.
Occurs massive and disseminated in decomposed granite rocks. Fracture fine earthy. Soft. Sp.gr. 2.2. Opaque. Dull. Colour yellowish and reddish-white.
Found in France, near Limoges and near Bayonne, and in Saxony, England, China, and other places.

q. CLAY, No. 202.
Phil. 55.56. Haid 3. 180.
Occurs massive. Structure earthy. Fracture uneven. Soft. Sp. gr. 1.8. 2.8. Opaque. Dull. Colour white, grey, brown, red, yellow, &c., of various shades, and striped, spotted, &c. Streak shining.
Found in all parts of the world.
The *Claystones* and *Slates* usually introduced into Catalogues of Minerals, appear too variable in their composition to admit of any distinct classification, and belong more properly to the geological series of rocks.

Siliciferous Sulphate of Alumina.

a. OLDHAMITE, No. 562.
An. 11.431.
Massive, and of the consistency of hog's-lard. Translucent. Colour, snow and milk-white. Taste, subacid. When exposed to the air, it dries and splits into long thin masses like starch, some of which are translucent and resemble gum arabic.
Found in a coal mine near Oldham in Lancashire.

Sulphate of Alumina.

a. WEBSTERITE. *Hallite*, No. 557.
Phil. 145. Haid. 3.70. Leon. 130.
Occurs in roundish or reniform masses, generally small. Fracture earthy. Soft, friable. Sp.gr. 1.7. Occasionally translucent, generally opaque. Colour white, sometimes yellowish. Streak white.
Found at Halle, in Prussia, in clay, and at Newhaven, Sussex, in limestone.

b. DAVITE, No. 558.
Q J. N S. 3.382. Leon. 433.
Occurs massive. Structure fine fibrous. Lustre silky. Colour white. Taste highly astringent. Very soluble.
Found near a warm spring which contains sulphuric acid, near Bogota, in Columbia.

Sulphate of Alumina and Potash.

a. ALUM, No. 559.
Haüy, 2.114. Phil. 196. Haid. 2.50. Leon. 107.
Occurs as an efflorescence, and sometimes in stalactites and fibrous masses.
Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron, indistinct. Fracture conchoidal. Hard. 2.0, 2.5. Sp.gr. 1.75. Transparent, translucent. Lustre vitreous. Colour yellowish or greyish-white. Streak white. Taste astringent, sweetish.
Found in many parts of Europe.

b. ALUM-STONE. *Tolfaite*, No 563.
Haüy, 2.128. Phil. 196. Haid. 2.67. Leon. 131.
Occurs in attached crystals and massive.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 92° 50′. Cleavage parallel to the primary planes, and more distinctly perpendicular to the axis. Fracture uneven. Hard. 5.0. Sp.gr. 2.7. Transparent, translucent. Lustre vitreous. Colour pale greyish and reddish-white. Streak white.
Massive varieties, amorphous, structure granular, compact.
Found at Tolfa, near Rome, in Tuscany, Naples, Hungary, and occasionally in the neighbourhood of active volcanoes.

AMBLYGONITE, No. 501.
Phil. 198. Haid. 3.70. Leon. 283.
Occurs massive.
Cleavage parallel to the lateral planes of a rhombic prism of about 105° 45′, and indistinctly oblique to its axis. Fracture uneven. Hard. 6.0. Sp.gr. 3.04. Translucent. Lustre vitreous, inclining to pearly. Colour greenish-white. Streak white.
Found near Chursdorf in Saxony, in Granite, accompanying Tourmaline and Topaz.

AMMONIA.

Muriate of Ammonia.

a. SAL AMMONIAC, No. 60.
Haüy, 2.221. Phil. 194. Haid. 2.39. Leon. 587.
Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the octahedron. Fracture conchoidal. Hard. 1.5, 2. Sp.gr. 1.528. Transparent to opaque. Colour white, grey, greenish, yellowish, and brownish. Lustre vitreous. Taste saline and pungent.
Massive varieties, stalactitic, botryoidal and reniform, with a fibrous structure, and occasionally in crusts.
Found in the neighbourhood of active volcanoes, and occasionally in other situations. It sometimes occurs in the beds of coal near Newcastle.

Sulphate of Ammonia.

a. MASCAGNIN, No. 523.
Phil. 194. Haid. 3.125. Leon. 127.
Stalactitic and efflorescent. Semitransparent to opaque. Colour yellow and yellowish-grey. Taste acrid, bitter.
Found in the neighbourhood of volcanoes.

AMPHIBOLE, consisting of the following varieties:—
Common Hornblende, colour dark green or greenish-black.
Basaltic Hornblende.
Foliated Augite of Werner.
Blue Hyperstene of Giesecke.
Green Diallage of Hauy; *Smaragdite.*
Pargasite in short green crystals.
Actynolite; the crystals green, slender, and sometimes radiating.
Tremolite; *Calamite*; *Grammatite*; colourless or green, or pink, or brownish-grey, generally imbedded in dolomite, frequently fibrous, and sometimes radiating
Amianthoide; *Byssolite.*
Amianthus. Asbestus. No. 275 to 278.
Haüy, 2.372. 454. 481. Phil. 63. 71. Haid. 2.271. Leon. 493.

Primary form an Oblique rhombic prism. P,M = 103° 13′ M,M′ = 124° 30′. Cleavage parallel to MM′, and less distinctly to the planes of modification *h* and *k*. Fracture uneven. Hard. 5.0, 6.0. Sp.gr. 2.93 to 3.2, or according to Phil. 3.6. Transparent to opaque. Lustre vitreous, sometimes pearly. Colour white to black. Streak greyish.

Massive varieties differ considerably in structure; from slaty to columnar and fibrous; the fibres sometimes, as in amianthus, being silky and flexible.

Found in all parts of the world, and in various geological positions.

AMPELITE. *Black Chalk*, No. 203.

Phil. 55. Haid. 3.181.

Occurs massive. Structure fine granular, slaty. Fracture fine earthy Soft. Sp.gr. 2.11, 2.18. Opaque. Dull. Colour black. Streak rather shining.

Found in several parts of Europe in rocks of clay-slate.

ANALCIME. *Cubicite*, No. 210.

Haüy, 3.170. Phil. 129. Haid. 2.227. Leon. 202.

Occurs in attached and imbedded crystals. Primary form a Cube. CRYST. fig. 56. Cleavage parallel to P indistinct, interrupted. Fracture uneven. Hard. 5.5. Sp.gr. 2.068. Transparent to translucent. Lustre vitreous. Colour white, sometimes greyish and reddish. Streak white.

Found in several parts of Scotland, and in many different places in other Countries, chiefly in basaltic and amygdaloidal rocks.

ANORTHITE, No. 228.

Haid. 3.71. Leon. 432.

Occurs in attached crystals.

Primary form a Doubly oblique prism, CRYST. fig. 95. P,M=94°; P,T=110° 50′; M,T=117° 42′. Cleavage parallel to P and T. Fracture conchoidal. Hard. 6. Sp.gr. 2.76. Transparent to translucent. Lustre vitreous, and on P and T rather pearly. Colour white. Streak white.

Found in cavities in masses of Limestone, ejected from Vesuvius.

ANTHOPHYLLITE, No. 304.

Haüy, 2.600. Phil. 69. Haid. 2.211. Leon. 514. 432.

Occurs in crystalline masses, with a fibrous columnar structure.

Cleavage parallel to the lateral planes of a Rhombic prism of 125°, and to both its diagonals, the bright plane being parallel to the greater diagonal, and another imperfect cleavage transverse, and apparently perpendicular to the axis of the prism.

Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 3.2, 3.3. Translucent. Lustre pearly, and inclining to Metallic. Colour yellowish-brown. Streak white.

Found in beds of mica slate at Kongsberg and Modum in Norway.

ANTIMONY.

Arseniuret of Antimony?

a. ARSENICAL ANTIMONY, No. 38.

Leon. 719.

Occurs in botryoidal forms. Structure scaly. Fracture granular. Sp.gr. 6.2. Opaque. Dull. Colour tin-white.

Found at Przibram in Bohemia.

Native Antimony.

NATIVE ANTIMONY, No. 25.

Haüy, 4.79. Phil. 329. Haid. 2.426. Leon. 684.

Occurs in reniform or amorphous masses, with a granular structure, the grains being crystalline and differing considerably in size.

Primary form a Rhomboid. CRYST. fig. 106. P,P′= 117° 15′, as inferred from cleavage, no regular crystals having yet been observed. Hard. 3.0, 3.5. Sp.gr. 6.646. Opaque. Lustre metallic. Colour tin-white. Streak the same.

Found in veins traversing ancient rocks, at Sahlberg in Sweden, at Allemont in Dauphiny, and at Andreasberg in the Hartz.

The arseniferous native antimony appears to be an accidental mixture of arsenic with native antimony.

Oxide of Antimony.

a. WHITE ANTIMONY. No. 409.

Haüy, 4 308. Phil. 331. Haid. 2.251. Leon. 335.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′=136° 58′. Cleavage parallel to M,M′. Lustre adamantine. Fracture indistinct. Hard. 2.5, 3.0. Sp.gr. 5.566. Translucent. Colour white, sometimes reddish or greyish. Streak white.

Massive variety, earthy, investing sulphuret and native antimony, and apparently produced by the decomposition of those Minerals.

Found in Bohemia, Saxony, Hungary, and France.

Sulphuret of Antimony.

a. GREY ANTIMONY, No. 93.

Haüy, 4.291. Phil. 329. Haid. 3. 23. Leon. 605.

Occurs in attached and aggregated crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 90° 45′. The crystals sometimes capillary and flexible, like silky fibres. Cleavage parallel to diagonal of the prism. Fracture uneven. Hard. 2.0. Sp.gr. 4.62. Opaque. Lustre metallic. Colour between lead and steel-grey, frequently with a yellow and blue tarnish. Streak the same.

Massive varieties, amorphous, structure large fibrous, foliated, compact.

Found in Hungary, France, England, Scotland, the Hartz, Saxony, and other places.

b. BLACK ANTIMONY? No. 94.

Leon. 719.

Occurs as a black powder in cavities in Hornstone.

Found at Joachimsthal in Bohemia.

Sulphuret of Antimony and Nickel.

a. HARTMANNITE, No. 96.

Haid. 3.131. Leon. 615.

Occurs in imbedded crystalline particles and masses.

Primary form, according to Haidinger, a Cube. CRYST. fig. 56. Cleavage parallel to P. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 6.451. Opaque. Lustre metallic. Colour whitish steel-grey. Streak the same.

Massive variety, amorphous. Structure granular.

Found in the Principality of Nassau.

Sulphuret of Antimony, Lead, and Iron.

a. JAMESONITE, No. 101.

Haid. 3.26. Leon. 748.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 101° 20′ nearly. Haid. Cleavage

parallel to P distinct, less so parallel to M. Fracture very indistinct. Hard. 2.0, 2.5. Sp.gr. 5.564. Opaque. Lustre metallic. Colour steel-grey, sometimes dark. Streak the same.

Massive variety, amorphous. Structure large to small fibrous.

Found in Cornwall and in Hungary, and probably in other places, where it has been considered a sulphuret of antimony.

Sulphuret of Antimony and Lead.

a. ZINKENITE, No. 99.

E.J.S. 6.17, 358.

Occurs in attached crystals, said to be regular hexagonal prisms, and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ uncertain. No cleavage. Fracture uneven. Hard. 3.0, 3.5. Sp.gr. 5.303. Opaque. Lustre metallic, bright. Colour steel-grey. Streak the same.

Found at Wolfsberg in the Hartz.

Sulphuret of Antimony and Iron.

a. BERTHIERITE, No. 102.

E.J.S. 7 353.

Occurs in confused laminated masses, or elongated imbedded prisms, resembling grey antimony. Colour dark steel grey inclining to brown.

Found at Chazelles in Auvergne.

Oxi-sulphuret of Antimony.

a. RED ANTIMONY, No. 410.

Haüy, 4.311. Phil. 331. Haid. 3.36. Leon. 608.

Occurs in thin, acicular crystals, generally radiating, sometimes promiscuously aggregated.

Primary form, according to Phillips, a Square prism, and according to Haidinger an oblique rhombic prism. One bright cleavage, and others less distinct. Hard. 1.0, 1.5. Sp.gr. 4.5. Translucent. Lustre adamantine. Colour dull red.

Found at Braunsdorff in Saxony, in Hungary, France, and in the Hartz.

APLOME, No 296.

Haüy, 2 538. Phil. 29. Haid. 2.364. Leon. 491.

Occurs in attached and imbedded dodecahedral crystals.

Primary form a Cube. CRYST. fig. 56. Surfaces of the Dodecahedron striated parallel to the edges of P. Cleavage imperfect parallel to P. Fracture uneven. Hard. 7.0, 7.5. Sp.gr. 3.444. Translucent, opaque. Lustre vitreo-resinous. Colour yellowish-brown.

Found in Saxony, Bohemia, Siberia, and in small crystals in England.

APOPHYLLITE. *Albin. Ichthyopthalmite. Tesselite. Oxahverite*, No. 204.

Haüy, 3.191. Phil. 110. Haid. 2 245. Leon. 213.

Occurs in attached crystals and massive.

Primary form a Square prism. CRYST. fig. 65. M,*a* = 109° 40′. Cleavage parallel to P, perfect; less so parallel to M. Fracture uneven. Hard. 4.5, 5.0. Sp.gr. 2.46. Transparent, translucent. Lustre vitreous. Colour white, occasionally with a yellowish, greenish, or reddish tinge. Streak white.

Massive variety, amorphous, structure laminar.

Found in the cavities of trap rocks, and occasionally in beds of the older formations, in the Faroe Islands, in India, Sweden, Norway, the Bromart, Bohemia, and some other places. The Oxahverite from Oxahver in Iceland.

ARFWEDSONITE, No. 279.

Phil. 377. Haid. 3. 73. Leon. 497.

Occurs massive amorphous. No crystalline form observed.

Cleavage parallel to the lateral planes, and both the diagonals of a Rhombic prism of 123° 55′. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 3.44. Opaque. Lustre vitreous. Colour black.

Found in Norway, and in Greenland associated with Sodalite.

ARSENIC.

Native Arsenic.

a. NATIVE ARSENIC, No. 27.

Haüy, 4.236. Phil. 275. Haid. 2.423. Leon. 676

Occurs in reniform stalactitic and amorphous masses, frequently in parallel layers. Structure fine granular. Fracture uneven. Hard. 3.5. Sp gr. 5.766. Opaque. Colour of fresh fracture greyish-tin-white, which afterwards becomes greyish-black. Streak shining.

Found in several parts of Saxony, in Bohemia, the Hartz, France, Norway, Transylvania, and other places; generally in metallic veins.

Oxide of Arsenic.

a. OXIDE OF ARSENIC, No. 465.

Haüy, 4.241. Phil. 375. Haid. 2.26. Leon. 333. 170.

Occurs in attached octahedral crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the octahedron. Fracture conchoidal. Sp.gr. 3.7. Translucent, opaque. Lustre nearly adamantine. Colour white, occasionally yellowish. Streak white. Taste sweetish astringent.

Massive varieties, reniform, botryoidal, stalactitic, and amorphous.

Found accompanying native arsenic in many mineral veins, and produced from the decomposition of other Minerals. Is soluble in water and a violent poison.

Red Sulphuret of Arsenic.

a. REALGAR, No. 108.

Haüy, 4 247. Phil. 277. Haid. 3.49. Leon. 602.

Occurs in attached crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 104° 6′, M,M′ = 74° 15′. Cleavage parallel to P and M. Fracture conchoidal.

Hard. 1.5, 2.0. Sp.gr. 3.556. Transparent, opaque. Lustre resinous. Colour red. Streak orange-yellow.

Massive varieties, amorphous, structure granular.

Found principally in Hungary and Transylvania, also in Saxony, Bohemia, and some other places.

Yellow Sulphuret of Arsenic.

a. ORPIMENT, No. 109.

Haüy, 4.247. Phil. 277. Haid. 3.47. Leon. 599.

Occurs in imbedded imperfect crystals and massive.

Primary form a Right rhombic prism. CRYST. fig 71. M,M′ = 100°. Cleavage parallel to the greater diagonal of the prism. Fracture uncertain. Hard. 1.5, 2.0. Sp.gr. 3.480. Translucent. Lustre resinous. Colour yellow. Streak paler yellow.

Massive varieties, botryoidal, reniform, nodular, sometimes granular, the structure of the grains or masses foliated, and the laminæ very flexible

Found in most of the districts which yield the red sulphuret, and is like that used as a pigment.

AURALITE, No. 330.
Occurs in apparently hexagonal prisms in felspar at Abo in Finland. Opaque. Colour dark brown.

AXINITE. *Thumite. Yanolite*, No 430.
Haüy, 2.559. Phil. 43. Haid. 2.341. Leon. 454.
Occurs in attached and imbedded crystals, and massive.
Primary form a Doubly oblique prism. CRYST. fig. 95. P,M = 134° 40′. P,T = 115° 17′. M,T = 135° 10′. Fracture uneven. Hard. 6.5, 7.0. Sp.gr. 3.27. Transparent, translucent. Lustre vitreous. Colour bluish, greyish, reddish-brown, of several shades. Streak white.
Massive varieties, amorphous, structure lamellar, granular.
Found in Dauphiny, and at Botallack in Cornwall, and in other places.

AZOTIC GAS, No. 44.
Is said to be contained in the Bath hot springs, and to rise with the vapour from the public bath.

AZURITE. *Klaprothite. Tyrolite. Voroulite*, No. 499.
Haüy, 3.54. Phil. 94. Haid. 2.290. Leon. 136.
Occurs in attached crystals and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 121° 30′. Cleavage indistinct. Fracture uneven. Hard. 5.0, 5.5. Sp gr. 3.056. Translucent, opaque. Lustre vitreous. Colour blue Streak white.
Massive varieties, amorphous, structure granular.
Found in Salzburg, and in rolled crystalline masses in Brazil.

AMPHODELITE, No. 331.
A Mineral found in Finland, having the form, cleavage, and colour of Latrobite.

BABINGTONITE, No. 332.
Haid. 3.75. Leon. 721.
Occurs in attached crystals.
Primary form a Doubly oblique prism. CRYST. fig. 95. P,M = 92° 34′. P,T = 88°. M,T = 112° 30′. Cleavage parallel to P and T. Fracture uneven. Hard. 5.5, 6.0. Faintly translucent. Lustre vitreous. Colour black, sometimes greenish.
Found at Arendal in Norway, associated with Cleavelandite.

BARYTES.

Carbonate of Barytes.

a. WITHERITE. *Barolite*, No. 438.
Haüy, 2.25. Phil. 182. Haid. 2.119. Leon. 330.
Occurs in attached crystals and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 118° 30′. Fracture uneven. Hard. 3.0, 3.5. Sp.gr. 4.3. Transparent, translucent. Lustre vitreo-resinous. Colour white, sometimes greyish or yellowish. Streak white.
Massive varieties, globular, botryoidal, reniform. Structure large, fibrous, sometimes granular.
Found principally in England, in Shropshire, Lancashire, Durham, and Westmoreland, and occasionally in small quantities in Siberia, Hungary, and other places.

Carbonate of Lime and Barytes.

a. BARYTO CALCITE, No. 443.
Haid. 3.76. Leon. 327.
Occurs in attached crystals and massive.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 102° 54′. M,M′ = 106° 54′. Cleavage parallel to P and M, distinct. Fracture uneven. Hard. 4 0. Sp.gr. 3.66. Transparent, translucent. Lustre vitreo-resinous. Colour white, sometimes yellowish or greenish. Streak white.
Massive varieties, amorphous. Structure granular.
Found at Alston Moor, Cumberland.

Sulphate of Barytes.

a. BAROSELENITE. *Bolognian Spar. Cauk*, No. 527.
Haüy, 2.5. Phil. 183. Haid. 2.121. Leon. 255.
Occurs crystallized and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 101° 42′. Cleavage parallel to P and M. Fracture conchoidal. Hard. 3 0, 3.5. Sp gr. 4 416, 4.7. Transparent, translucent. Lustre vitreous. Colour white, blue, yellow, brown. Streak white.
Massive varieties, occasionally globular, reniform, amorphous. Structure fibrous, granular, compact.
Found in several localities in most Countries, and in different geological positions.

Sulphate of Barytes and Fluate of Lime.

a. BARYTO-FLUORITE, No. 528.
An. 16.48.
Occurs in a vein in coarse shell limestone in Derbyshire, and nearly resembles fine compact grey limestone. Hard. 4. Sp gr. 3.75.

BERGMANNITE. *Spreüstein. Radiolite of Esmark*, No. 333.
Haüy, 4.484. Phil. 290. Haid .3.77. Leon. 474.
Occurs massive, amorphous. Structure fibrous, sometimes radiating. Hard. 7.0, 7.5. Sp.gr. 2 3 Opaque. Colour greyish-white, dull yellow, and red. Lustre pearly.
Found near Stavern in Norway.

BIOTINE, No. 334.
The crystals of this substance appear to correspond in form and measurement with those of Anorthite, of which they will probably be found to be a variety.

BISMUTH.

Arseniuret of Bismuth?

ARSENICAL BISMUTH, No. 34.
Haid. 3.74. Leon. 720.
Occurs in aggregations of small globular forms. Structure fibrous or curved lamellar. Fracture uneven. Soft. Heavy. Lustre resinous. Colour dark hair-brown.
Found at Schneeberg in Saxony.

Carbonate of Bismuth.

AGNESITE, No. 456.
B.M. Tab. 344. Phil. 271. Leon. 787.
Resembles steatite, but more earthy, and harsher to the touch.
Found at St. Agnes, Cornwall.

Silicious Carbonate of Bismuth.

BISMUTH-BLENDE, No. 457.
E J.S. 7.342.
Occurs in attached crystals, and in globular and stalactitic masses.
Primary form a Cube. CRYST. fig. 56. Cleavage imperfect. Fracture conchoidal. Hard. 4.5, 5.0. Sp.gr. 5.9, 6 0. Translucent, opaque. Lustre bright resinous. Colour reddish and yellowish-brown. Streak yellowish-grey.
Found at Schneeberg in Saxony.

NATIVE BISMUTH, No. 9.
Haüy, 4.202. Phil. 272. Haid. 2.433 Leon. 693.

Mineralogy

Occurs crystallized and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to planes of *Mod. a.* Fracture indistinct. Hard. 2.01, 2.5. Sp.gr. 9.737. Opaque. Lustre metallic. Colour of fresh cleavage reddish-silver-white, but tarnishes on exposure to air. Streak unchanged.

Massive varieties, amorphous, structure granular.

Found in several mines in Saxony, and in most other mining districts of Europe.

Oxide of Bismuth.

a. BISMUTH OCHRE, No. 137.

Haüy, 4.214. Phil. 274. Leon. 561.

Occurs massive, amorphous, sometimes minutely disseminated. Fracture earthy. Soft. Sp.gr. 4.7. Opaque, Dull. Colour greenish or greyish-yellow.

Found in Saxony and Bohemia.

Seleniuret of Bismuth and Tellurium.

a. BASINATITE, No. 46. Leon. 589.

Occurs in small, imbedded, laminated masses. Sp.gr. 7.8 Lustre metallic. Colour between steel and lead-grey.

Found at Bastnaes in Sweden.

Sulphuret of Bismuth.

a. BISMUTH GLANCE, No. 84.

Haüy, 4 210. Phil. 273. Haid. 3.19. Leon. 616.

Occurs in attached and imbedded crystals, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M' about 91°. Cleavage parallel to P, and to the greater diagonal of the prism. Fracture indistinct. Opaque. Lustre metallic. Colour lead to steel-grey. Streak the same.

Massive varieties, amorphous, structure granular or fibrous, the fibres promiscuously aggregated.

Found sparingly in Saxony, Bohemia, Hungary, and some other places in Europe, and in England in Cornwall and Cumberland.

Sulphuret of Bismuth and Copper.

a. CUPREOUS BISMUTH, No. 85.

Phil. 271. Haid. 3.91. Leon. 619.

Occurs massive. Structure small-fibrous. Fracture uneven. Opaque. Lustre metallic. Colour lead-grey to steel-grey.

Found at Fürstenberg, in veins accompanying other ores of bismuth, cobalt, &c.

Sulphuret of Bismuth, Lead, and Copper.

a. NEEDLE ORE, No. 86.

Phil. 274. Haid. 3.130. Leon. 618.

Occurs in imbedded prismatic crystals, in quartz.

Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 6.125. Opaque. Lustre metallic. Colour dark lead-grey.

Found near Catharinenburg in Siberia.

Sulpho-telluret of Bismuth.

a. BORNITE. *Telluret of Bismuth*, No. 20.

Occurs in imbedded, imperfect, rhombic and hexagonal crystals, and small foliated masses.

Primary form a Rhomboid. CRYST. fig. 106. The crystals macled in several directions. Cleavage perpendicular to the axis, very distinct Sp.gr. 7.5. Lustre highly metallic. Colour bright steel-grey.

Found at Schoubkan, near Schemnitz, Hungary.

BORACIC ACID. *Sassolin*, No. 423.

Haüy, 1.297. Phil. 144. Haid. 2.25. Leon. 146.

Occurs naturally in scaly or granular crystalline aggregations, which are very friable.

Translucent. Lustre pearly. Colour greyish and yellowish-white. Streak white. Taste slightly acid and bitter. Sp.gr. 1.480.

Found at Volcano, one of the Lipari Islands, and in other volcanic districts.

BOVELITE. *Pseudo Sommite*, No. 335.

Phil. 126. Leon. 468.

Occurs in attached hexagonal prisms.

Primary form a Rhomboid. CRYST. fig. 106. Transparent. Lustre vitreous. Colour white. Streak white.

Found at Capo di Bova, near Rome, and has hitherto been distinguished from Nepheline only by its *not gelatinizing in acids* as that Mineral does. Its secondary forms, if observed, have not been described.

BREISLAKITE, No. 568.

Haid. 3.80. Leon. 723.

Occurs in capillary brownish fibres, covering and filling cavities in some of the substances ejected from Vesuvius. It is said to contain a considerable portion of copper, but its other constituents are not known.

BREWSTERITE, No. 216

Phil. 200. Haid. 3.80. Leon. 193, 723.

Occurs in attached crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M about 92°, M,M' = 136°. Cleavage parallel to the oblique diagonal. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 2.2. Transparent, translucent. Lustre vitreous. Colour yellowish and greyish-white, and occasionally colourless.

Found at Strontian in Scotland.

BRONZITE. No. 286.

Haüy, 2.455. Phil. 25.71. Haid. 2.207. Leon. 518.

Occurs in massive aggregations of columnar crystals.

Cleavage parallel to the lateral plane and both diagonals of a Rhombic prism of 93° 30'. Fracture uneven. Hard. 4.0, 5.0. Sp.gr. 3.25. Translucent. Lustre vitreous, pseudo-metallic on cleavage planes. Colour greenish or greyish-brown. Streak lighter colour.

Found in serpentine in Stiria, in greenstone in the Hartz, and in other places.

BUCKLANDITE, No. 336.

An. N.S. 7.134. Haid. 3.83. Leon. 725.

Occurs in attached crystals.

Primary form an Oblique rhombic prism. P,M = 103° 56'. M,M' = 70° 40'. Levy. Opaque. Colour dark brownish-black.

Found near Arendal in Norway, and at Laach on the Rhine.

BUSTAMITE, No. 274.

S. 18.392.

Structure bladed. Hard. 6.5. Sp.gr. 3.1, 3.3. Nearly opaque. Colour grey, greenish, and reddish.

Found in Mexico.

CADMIUM. A metal found in small quantities accompanying zinc in several of its ores, particularly in the fibrous blende from Przibram in Bohemia.

CARBON.

A. DIAMOND, No. 40.

Haüy, 4.419. Phil. 361. Haid. 2.306. Leon. 669.

Mineralogy

Occurs in imbedded crystals in alluvial ground.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron, very distinct. Fracture conchoidal. Hard. 10.0. Sp.gr. 3.52. Transparent, but sometimes rendered opaque by foreign matter. Lustre adamantine. Colour white, sometimes grey, blue, green, yellow, red, brown, black. Streak greyish.

Found in the East Indies and in Brazil.

B. COAL.

a. *Not bituminous.* ANTHRACITE, No. 41.

Haüy, 440. Phil. 364. Haid. 3.64. Leon. 672. 803.

Occurs massive, amorphous. Structure columnar, compact. Fracture conchoidal. Hard. 2.0, 2.5. Sp.gr. 1.4, 1.5. Opaque. Lustre imperfect metallic. Colour grey to iron-black. Streak the same.

Found in most Countries.

b. *Bituminous*, No. 586.

Haüy, 4.159, 470. Phil. 370, 371. Haid. 3.61. Leon.

This includes the *common*, the *Cannel*, and all the varieties of fossil coal.

Occurs massive, amorphous. Structure foliated, granular, compact, earthy, and resembling wood. Fracture conchoidal, uneven. Lustre resinous, of different degrees. Colour black, brown, brownish, and greenish-yellow.

Found in most parts of the World, associated with vegetable organic remains.

c. *Wood Coal.* LIGNITE. No. 574.

Phil. 372.

Occurs massive. Structure fibrous, compact, resembling wood. Fracture of some varieties conchoidal. Opaque. Lustre resinous, dull. Colour brown, of several shades, to black.

Found in several parts of Europe and America.

d. *Paper Coal.* DYSODILE. No. 575.

N.J. 24 223. Phil. 372.

Occurs in amorphous masses. Structure foliated, the leaves thin and a little flexible. Sp.gr. 1.146. Opaque, but becomes translucent after immersion in water. Colour greenish and yellowish-grey. When burned it produces a strong and fetid bituminous odour.

Found in a thin stratum between two beds of secondary limestone at Melilli, near Syracuse in Sicily.

C. BITUMEN.

Haüy, 4 452. Phil. 366 to 369. Haid. 3.59. Leon. 797. 799. 801.

a. *Liquid.* NAPHTHA. No. 580.

Transparent. Colourless, or slightly tinged with yellow. Odour peculiar, termed bituminous.

Found chiefly on the coast of the Caspian Sea.

b. *Viscid.* PETROLEUM, No. 581.

Slightly translucent. Colour dark reddish-brown. Odour bituminous.

Found in many parts of Europe and America, but chiefly in Asia, flowing from beds associated with coal strata. As much as 400,000 hogsheads is said to be collected annually in the Birman Empire. It is also abundant in Persia.

c. *Elastic.* ELATERITE, No. 582.

Soft, flexible. Opaque. Colour brown, sometimes greenish. Odour bituminous.

Found only in the Odin mine, near Castleton, Derbyshire.

d. *Earthy.* MALTHA.

Less free from extraneous matter than the preceding varieties, to which circumstance it probably owes its earthy character.

Fracture uneven. Soft. Opaque. Colour blackish-brown. Odour bituminous.

Found chiefly in Persia, and less frequently in other places than the other varieties.

e. *Earthy, containing Benzoic Acid.* MURINDO.

Q.J. N.S. 3 387.

Occurs massive. Fracture earthy. Yields to the nail. Floats in water. Opaque. Dull. Colour externally blackish-brown, internally lighter. Tastes hot and peculiar. Smell pungent.

Found at Murindo, Province of Choco, Columbia.

f. *Compact.* ASPHALTUM. *Jew's Pitch*, No. 585.

Fracture conchoidal. Hard. 2. Sp.gr. 1.16. Opaque. Lustre vitreous, resinous. Colour brown to black.

Found in Albania, on the shores of the Dead Sea, in considerable quantities; in the Islands of Barbadoes and Trinidad, and occasionally in other places.

It is supposed to have been used by the Egyptians in embalming the bodies of the dead, and has been employed in the West Indies instead of pitch for calking the bottoms of ships.

These varieties of bitumen pass by insensible degrees from the transparent fluid to the opaque solid, and hence they are regarded as appertaining to the same Mineral species.

D. RETINASPHALTUM, No. 577.

Phil. 375. Haid. 3.146. Leon. 793.

Occurs in amorphous lumps of different sizes, imbedded in wood coal. Fracture imperfect, conchoidal. Hard. 1.5, 2.0. Sp.gr 1 135. Opaque. Lustre resinous. Colour pale brownish-yellow.

Found at Bovey Tracey, Devonshire, and is also said to have been found at Halle and some other places on the Continent, accompanying earthy brown coal, and of different colours.

E. FOSSIL COPAL. *Highgate Resin*, No. 578.

Phil. 375.

Found in blue clay at Highgate near London, and at Wolchow in Moravia, in small nodular masses. Fracture conchoidal. Sp gr. 1.046. Nearly opaque. Lustre resinous. Colour dull brown.

F. AMBER, No. 576.

Phil. 373. Haid. 3.57. Leon. 791.

Occurs in nodular masses, sometimes very small. Fracture conchoidal. Hard. 2.0, 2.5. Sp gr. 1.08. Transparent to opaque. Lustre resinous. Colour yellowish-white, brown, red, yellow. Streak white.

Found on the coasts in the Baltic, and in beds of wood coal in several places in Europe and other Countries.

G. HATCHETINE. *Mineral Adipocire*, No. 579.

An. 1.136. Phil. 374. Haid. 3.106. Leon. 795.

Occurs in thin flakes and in granular masses in cavities of lime or ironstone. Very soft and light. The flakes translucent, with a slightly *glistening* and pearly lustre, the granular masses opaque and dull. Colour yellowish-white, and wax and greenish-yellow, without odour and not elastic. Combustible.

Found at Merthyr Tydvil in South Wales.

H. NATIVE NAPHTHALINE, No. 587.

Q.J. 4.446.

Occurs crystalline, cleavable in some directions, with

a conchoidal fracture in others. Sp.gr. 1.0, 1.5. Transparent. Lustre adamantine. Colour white, yellow, green. Has the appearance of Talc.

Found in the fissures of bituminous wood in the coal formation of Urnach, Canton of St. Gall.

r. SCHERERITE, No. 588.

Q.J. 5.431.

Occurs between the fibres of fossil wood in acicular crystals, and small layers. Translucent. Lustre nacreous. Colour white or yellowish white.

Found at Urnach, Canton of St. Gall, Swisserland, in a coal formation.

CAVOLINITE, No. 337.

The crystalline forms of this Mineral correspond very nearly with those of Nepheline and Davyne; but its lustre is highly pearly instead of vitreous, and it may be cleaved with much greater facility. It is found at Mount Vesuvius.

CEREOLITE, No. 338.

The Marquis de Dree first gave this name to a soft yellowish waxy looking substance occurring in a greyish matrix, in small irregular nodules. Several other soft Minerals, differing in many of their characters from that of De Dree, have since passed under the same name, but there do not appear to be any published descriptions or analyses of them.

De Dree's Mineral was found near Lisbon.

CERIUM.

a. CARBONATE OF CERIUM, No. 455

E.J.S. 3.331. Leon. 726.

Occurs in white crystalline coatings on the Cerite of Bastnaes, in Sweden.

b. FLUATE OF CERIUM, No. 509.

Phil. 266. Haid. 3.100. Leon. 571.

Is said to occur in six-sided prisms, plates, and amorphous masses. Colour reddish. No other characters given.

Found very sparingly at Finbo, Broddbo, and Bastnaes, near Fahlun, in Sweden.

c. SUB-FLUATE OF CERIUM, No. 510.

Phil. 266. Haid. 3.101. Leon. 243.

Resembles porcelain jasper, but with traces of crystallization. Colour yellow.

Found at Finbo in Sweden.

d. FLUATE OF CERIUM AND YTTRIA, No. 511.

Phil. 267. Haid. 3.101.

Occurs in small imbedded masses, and sometimes thinly investing Gadolinite. Earthy. Soft. Colour red, of different shades, yellow, white.

Said, by Berzelius, to be a mechanical mixture of the fluates of yttria and of cerium with silica.

e. YTTRO-CERITE. *Fluate of Cerium, Yttria, and Lime,* No. 512.

Phil. 265. Haid. 3.172. Leon. 573.

Occurs massive, structure granular, compact. Fracture uneven. Hard. 6.5. Sp.gr. 3.447. Opaque. Colour violet-blue, greyish-red, and greyish-white.

Found at Finbo and Broddbo in Sweden.

f. SILICATE OF CERIUM. No. 171.

E.J.S. 6.357. Leon. 227.

Occurs in small imbedded nodules and hexagonal prisms, in magnesian carbonate of lime. Cleavage parallel to the lateral planes. Fracture uneven. Translucent. Colour pale yellowish-brown.

Found at Santa Fé de Bogota, accompanying the precious Emeralds from that locality.

Silicate of Cerium and Iron.

a. CERITE, No. 170.

Haüy, 4.393. Phil. 263. Haid. 2.394. Leon. 227.

Occurs in amorphous imbedded masses. Structure fine granular. Fracture uneven. Hard. 5.5. Sp.gr. 4.912. Slightly translucent. Lustre resinous. Colour pale dull red, sometimes greyish. Streak white.

Found near Riddarhittan in Sweden, imbedded in or accompanying Cerine.

b. CERINE, No. 319.

Haüy, 4.395. Phil. 265. Haid. 2.395. Leon. 481.

Occurs massive, and rarely in attached imperfect crystals. Hard. 5.5, 6.0. Sp gr. 4.173. Opaque. Lustre imperfect metallic. Colour brownish black. Streak brownish-grey.

Found near Riddarhittan in Sweden.

c. ALLANITE, No. 320.

Haid. 3.68. Leon. 481.

Occurs crystallized and massive.

Primary form is said by Phillips to be a Square prism, and by Haidinger, a Doubly oblique prism, whence it appears that two different Minerals have been described under the same name. Fracture, according to Haidinger, imperfect conchoidal. Hard. 6.0. Sp gr. 4.0. Opaque. Lustre imperfect metallic. Colour brownish-black. Streak greenish-grey.

Found at Alluk, East Greenland.

The Allanite of Phillips is probably the Fergusonite of Haidinger.

Silicate of Cerium, Iron, Alumina, and Lime.

a. ORTHITE, No. 327.

Phil. 265. Haid. 3.133. Leon. 210.

Occurs in small, slender, columnar, imbedded masses. Fracture conchoidal. Hard. 6.0, 7.0. Sp.gr. 3.288. Opaque. Lustre vitreous. Colour brownish-black. Streak brownish-grey.

Found at Finbo in Sweden, in a granitic vein, traversing gneiss, and, in larger imbedded masses, in Finland.

b. PYRORTHITE, *containing Carbon*, No. 328.

Phil. 265. Haid. 3.142. Leon. 773.

Occurs in single or aggregated, slender, columnar masses, imbedded in granite or quartz. Fracture conchoidal, uneven, earthy. Haid. 2.5. Sp.gr. 2.19. Opaque. Lustre resinous. Colour brownish-black. the same.

Found near Fahlun in Sweden.

CHABASIE, No. 205.

Haüy, 3.163. Phil. 138. Haid. 2.232. Leon. 198.

Occurs in attached crystals.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ =94° 46′. Cleavage parallel to P, nearly distinct. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 2.1. Transparent, translucent. Lustre vitreous. Colour white, sometimes reddish or yellowish. Streak white.

Found in the Faro Islands, in Iceland, in many parts of Europe, and in America.

CHIASTOLITE. *Crucite. Macle,* No. 186.

Haüy, 2.365. Phil. 201. Haid. 3.84. Leon. 726.

Occurs in imbedded crystals in clay-slate.

Primary form unknown. The crystals are nearly

Square prisms, composed of a greyish or reddish substance, enclosing a central black prism, and occasionally four others within its lateral edges, connected with the central one by four black thin plates.

Cleavage parallel to the lateral planes. Fracture splintery. Hard. 5.0, 5.5. Sp.gr. 2.944. Translucent, opaque. Lustre vitreo-resinous. Colour greyish and yellowish, or reddish-white. Streak white.

Found in many parts of Europe and America.

CHILDRENITE, No. 502.

Q.J.S. 16.274. Haid. 3 85. Leon. 137. 728.

Occurs in minute attached crystals.

Primary form a Right rhombic prism. M,M=92° 48′. Fracture uneven. Hard. 4.5, 5.0. Transparent, translucent. Lustre vitreous. Colour yellow. Streak white.

Found in the neighbourhood of Tavistock in Devonshire, and at Crinnis in Cornwall.

CHLOROPHAEITE, No. 173.

Macculloch, Western Isles, 1.504. Phil. 202. Haid. 3.86. Leon. 729.

Occurs in small masses imbedded in basalt. Fracture conchoidal. May be scratched by a quill. Sp.gr. 2.02. Transparent, opaque. Lustre vitreous. Colour green when first broken, but afterwards becomes black.

Found in the Isle of Rum, in Fifeshire, and in Iceland.

OXIDE OF CHROME, No. 419.

Phil. 271. Leon. 557.

Occurs in compact or pulverulent masses, coating or filling cavities in the chromate of iron at Unst, one of the Shetland Isles. Structure of the compact approaches to crystalline. Translucent. Lustre resinous. Colour grass-green and pale-yellow.

It is also found colouring granular quartz at Ecouchetz in Burgundy.

CHRYSOBERYL. *Cymophane*, No. 324.

Haüy, 2.303. Phil. 89. Haid. 2.304. Leon. 539.

Occurs in loose crystals in alluvial deposits in Brazil, and in imbedded crystals at Haddam and Saratoga, North America.

Primary form a Right rhombic prism. M,M′=120°. Cleavage parallel to P, and to the short diagonal of the prism. Fracture conchoidal. Hard. 8.5. Sp.gr. 3.754. Transparent, translucent. Lustre vitreous. Colour yellowish and brownish-green. Frequently with a bluish opalescence. Streak white.

Found in Brazil and North America.

CHUSITE, No. 339.

Phil. 202. Leon. 533.

A Mineral found by Saussure in the porphyritic rocks near Limbourg, and imperfectly described as occurring massive or granular. Translucent. Lustre greasy.

CLEAVELANDITE. *Albite. Silicious Spar*, No. 227.

Haüy, 3.70. Phil. 113. Haid. 2.255. Leon. 417.

Occurs in attached crystals and massive.

Primary form a Doubly oblique prism. P,M=93° 30′. P,T=115°. M,T=119° 30′. Cleavage parallel to the primary planes. Fracture uneven. Hard. 6.0. Sp.gr. 2.61, 2.68. Transparent, translucent. Lustre vitreous. Colour white, grey, pale blue, greenish, red. Streak generally white.

Massive varieties amorphous. Structure laminar.

Found in Dauphiny, at St. Gothard, and generally accompanying felspar in most of its numerous localities.

COBALT.

Arseniate of Cobalt.

a. RED COBALT. *Cobalt bloom*, No. 472.

Haüy, 4.232. Phil. 281. Haid. 2.181. Leon. 162.

Occurs sometimes in attached thin crystals, but generally as fine fibres, forming small globular tufts, or evenly coating the matrix, and also pulverulent and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M=101° 13′. M,M′=55° 15′. Cleavage parallel to a plane passing through the oblique diagonal, very distinct. Hard. 1 5, 2 0. Sp gr. 2.948. Transparent, translucent. Lustre vitreous. Colour red, of various shades, sometimes pearl or greenish-grey. Streak lighter colour. Splits easily into thin laminæ, which are very flexible.

Massive variety amorphous; structure fibrous, often radiating.

Found principally in Saxony and Bohemia.

b. ROSELITE? No. 473.

An. N.S. 8 439.

Occurs in attached crystals on greyish quartz.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′=125° 7′. Cleavage parallel to P. Fracture conchoidal. Hard. 3.0. Translucent. Lustre vitreous. Colour deep rose-red.

Found at Schneeberg in Saxony.

Arseniuret of Cobalt.?

a. WHITE COBALT, No. 29.

Haüy, 4.219. Phil. 278. Haid. 2.452. Leon. 654. 680.

Occurs in imbedded crystals, generally single, and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the primary planes, very distinct. Fracture uneven. Hard. 5.5. Sp.gr. 6.3. Lustre metallic. Colour silver-white. Streak greyish-black.

Massive variety amorphous; structure granular.

Found in Norway; in fine crystals at Tunaberg in Sweden; in Silesia, and in Cornwall.

b. HARD WHITE COBALT, No. 30.

E.N.P.J. 3.271.

Occurs crystallized. Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the cube distinct; less so parallel to *Mod. a*, and still less parallel to *Mod. e*. Sp.gr. 6.74, 6.84. Distinguished from white cobalt by its more distinct cleavage and greater sp.gr.

Found at Skutterud in Norway.

c. RADIATED WHITE COBALT, No. 31.

Haid. 2.454. Leon. 162?

Is said to crystallize in Rhombic prisms, but no distinct characters of it have been given.

Found at Schneeberg in Saxony.

d. RHOMBIC WHITE COBALT, No. 32.

Found at Hokambo in Sweden, having the bright lustre of arsenical cobalt, and the form and measurements of arsenical iron. No analysis or description has been given.

Sulpho-arseniuret of Cobalt and Iron.

a. GREY COBALT, No. 43.

Haüy, 4.225. Phil. 278. Haid. 2.455. Leon. 6.80.

Occurs in attached crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the plane of the Cube, Octahedron, and Rhombic dodecahedron, indistinct. Fracture uneven. Hard. 5.5. Sp.gr. 6.466. Lustre metallic. Colour greyish-tin-white. Streak greyish-black.

Massive varieties, reticulated; amorphous. Structure granular, compact.

Found principally at Schneeberg in Saxony, and in Bohemia. Used in the manufacture of Smalt.

b. *Grey cobalt?* No. 114.

Brit.Min. tab. 472.

Is described as amorphous. Fracture uneven, like broken steel, and very brittle. Sp.gr. 5.5, 7.2. Lustre metallic. Colour rather dull steel-grey. Streak brighter.

Found at Dolcoath mine in Cornwall.

The white and grey ores of cobalt require a more precise examination than they have hitherto received, which will probably separate them into distinct species.

Cobalto-bismuthic Arsenic.

a. KERSTENITE, No. 33.

E.J.S. 6.355. Leon. 720 ?

Massive. Structure fibrous, imperfect radiated, rather porous. Sp.gr. 6.0, 6.7. Lustre nearly metallic. Colour between lead-grey and steel-grey.

Found at Schneeberg in Saxony.

Oxide of Cobalt and Manganese.

a. EARTHY COBALT. *Cobalt ochre*, No. 129.

Haüy, 4.230. Phil. 281. Haid. 3.78. Leon. 162.3, 238.9.

Occurs in botryoidal, stalactitic, and amorphous masses. Structure fine granular, earthy. Soft. Sp.gr. 2.2. Opaque. Colour bluish-black, brownish, and yellowish. Streak shining.

Found in Hessia, Thuringia, and other depositaries of the ores of cobalt.

It is not improbable that the brown and yellow varieties may upon further examination appear not to belong to one species.

Sulphate of Cobalt.

a. SULPHATE OF COBALT, No. 547.

Phil. 282. Haid. 3.145. Leon. 114.

Occurs in small globular, stalactitic, and amorphous masses, thinly investing other Minerals. Soft. Soluble in water. Translucent. Lustre vitreous, often dull externally. Colour pale rose-red.

Found among the mining heaps of old mines at Bieber, near Hanau, and in Salzburg.

Sulphuret of Cobalt.

a. SULPHURET OF COBALT, No. 75.

Phil. 280. Haid. 3.88. Leon. 653.

Occurs in imbedded amorphous masses. Structure fine granular, compact. Fracture uneven. Lustre metallic. Colour steel-grey, with a reddish tarnish. Streak grey.

Found at Riddarhittan in Sweden.

COMPTONITE, No. 340.

Phil. 201. Haid. 3.89. Leon. 193. 730.

Occurs in attached crystals in the cavities of fragments of an amygdaloidal rock at Vesuvius.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 91°. Cleavage parallel to both diagonals of the terminal planes. Fracture uneven. Hard. 5.0, 5.5. Transparent, translucent. Lustre vitreous. Colour white. Streak white.

Found at Vesuvius, and in a trap rock in Bohemia.

CONDRODITE. *Brucite. Maclureite*, No. 515.

Haüy, 2.476. Phil. 97. Haid. 3.87. Leon. 533.

Occurs in imbedded, rounded nodules of various sizes, generally small, the larger ones sometimes protruding into cavities in the matrix, and presenting crystalline forms not yet described.

Cleavage described as parallel to the lateral planes of a Rhombic prism of 124°. Fracture uneven. Hard 6.5. Sp.gr. 3.2, 3.5. Transparent, translucent. Lustre vitreous. Colour yellow to brown.

Found in Finland, and in several parts of North America. And it is probable, from the difference in appearance of different specimens, that the name has been given to two or more different substances.

COPPER.

Arseniate of Copper.

Right prismatic.

a. LINSENERZ. *Octahedral Arseniate*, No. 477.

Haüy, 3.509. Phil. 316. Haid. 2.160. Leon. 172.

Occurs in attached, obtuse, octahedral crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 107° 5′. Levy. Cleavage parallel to the primary planes. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 2.926. Transparent, translucent. Lustre vitreous. Colour light blue and occasionally dull green. Streak pale blue or green.

Found in Cornwall near Redruth, and in Hungary.

b. OLIVENITE. *Olivenerz*, No. 478.

Haüy, 3.510. Phil. 319. Haid. 2.164. Leon. 168

Occurs crystallized and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 110° 30′. Levy. Cleavage parallel to the primary planes. Fracture uneven. Hard. 3.0. Sp.gr. 4.28. Transparent, translucent. Lustre vitreous, bright. Colour various shades of green, generally inclining to olive. Streak paler green.

Massive varieties, globular, reniform, nodular. Structure fibrous, occasionally granular, compact.

Found in Cornwall near Redruth, and near Alstonmoor in Cumberland.

c. EUCHROITE, No. 479.

Haid. 3.94. Leon. 173.

Occurs in attached or imbedded crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 117° 20′. Cleavage parallel to M indistinct. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 3.39. Transparent, translucent. Lustre vitreous. Colour *emerald*-green. Streak lighter green.

Found at Libethen in Hungary.

Oblique prismatic.

a. TRIEDRAL *Arseniate* of Bournon, No. 480.

Phil. 318. Haid. 3.144. Leon. 170.

Occurs crystallized and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 95°. M,M′ = 56°. Cleavage parallel to P. Fracture indistinct. Hard. 2.5, 3.0. Sp.gr. 4.2. Transparent, translucent. Lustre vitreous. Colour dark blue to blackish-green. Streak paler green.

Massive varieties, reniform, amorphous, with a lamellar structure.

Found in Cornwall near Redruth.

Rhomboidal.

a. COPPER MICA, No. 481.

Haüy, 3.509. Phil. 317. Haid. 2.178. Leon. 171.
Occurs in attached crystals.
Primary form a Rhomboid. CRYST. fig. 106. P,P′= 69° 48′. Levy. Crystals usually tabular, thin. Occasionally in floriform groups. Cleavage distinct, perpendicular to the axis, less so parallel to P. Fracture uneven. Hard. 2.0. Sp.gr. 2.549. Transparent, translucent. Lustre vitreous. Colour emerald-green. Streak rather pale green.
Found in Cornwall near Redruth.

Not Crystallized.

a. ERINITE, No. 482.
E.J.S. 9.93.
Occurs in concentric layers, between which other arseniates are found. No crystals observable. The surface of the layers rough, the fracture uneven, with slightly resinous lustre. Hard. 4.5, 5.0. Sp.gr. 4.04. Slightly translucent. Colour emerald-green. Streak paler green.
Found near Limerick.

b. CONDURRITE, No. 483.
P.M. and An. 2.286.
Considered by Mr. Phillips to be an accidental deposit resulting from the decomposition of other ores containing copper and arsenic.
Amorphous. Fracture conchoidal. Scratched by glass. When cut by a knife a polished lead-grey surface is produced. Sp.gr. 5.20. Opaque. Surface of fracture very smooth. Colour brownish-black. Streak black.
Found in Condurrow Mine, near Camborne, Cornwall.

Arseniuret of Copper? No. 35.

P.M. and An 2. 287.
Metallic. Amorphous. Yields to the knife. Malleable. Colour tin-white.
Found in Condurrow mine, near Camborne, Cornwall, accompanying and coated by Condurrite.

Carbonate of Copper.

a. BLUE CARBONATE OF COPPER, No. 461.
Haüy, 4.3. Phil. 309. Haid. 2.167. Leon. 152.
Occurs crystallized and massive.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 91°30′, M,M′ = 98° 50′. Cleavage parallel to P, dull, and also to M, and both diagonals, and to *e.* CRYST. fig. 83. Fracture uneven. Structure fibrous, large or small, parallel or diverging, sometimes curved, and lamellar transversely to the direction of the fibres. Occasionally granular, sometimes earthy. Hard. 3.5, 4.0. Sp.gr. 3.83. Transparent, translucent. Lustre vitreous, bright. Colour various shades of blue. Streak paler blue.
Massive varieties, globular, botryoidal, reniform, stalactitic.
Found in fine crystals at Chessy, near Lyons in France, in Siberia, the Bannat, Cornwall, and many other places.

b. MALACHITE. *Green Carbonate of Copper*, No. 460.
Haüy, 3.488. Phil. 310. Haid. 2.175. Leon. 155.
Occurs crystallized and massive.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 112° 33′. M,M′ = 107° 16′. The crystals generally acicular, and too slender for measurement. Cleavage parallel to P and to the oblique diagonal of the terminal planes. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 4.0. Transparent, translucent. Lustre vitreous, bright. Colour various shades of green. Streak paler green.
Massive varieties, amorphous, or in tuberose, globular, reniform, botryoidal, and stalactitic shapes. Structure fibrous, the fibres sometimes so slender as to appear compact, and then producing a silky lustre, and yielding a conchoidal fracture.
Found in the same places, generally, as the blue carbonate.
Crystals of green carbonate sometimes occur under the forms of blue carbonate and of red oxide, from which they have been produced by some natural process in the mine. These are termed Epigene by Haüy.

c. ANHYDROUS CARBONATE OF COPPER, No. 463.
Phil. Tr. 1814, p. 45. An. 16. 39.
Occurs amorphous. Structure imperfectly foliated. Fracture small-conchoidal. Easily scratched with a knife. Sp.gr. 2.62. Colour dark blackish-brown. Streak reddish-brown.
Found in India, N.W. of Madras, accompanying Malachite.

Carbonate of Copper and Zinc.

a. KUPFERSCHAUM, No. 464.
Haid. 2.180. Leon. 756.
We believe that two or more different Minerals, presenting nearly the same external characters, have been included by different authors under this name.
The Mineral here alluded to consists of small, silky tufts or globules, composed of very thin radiating leaves or leafy fibres, without any appearance of crystalline form, or any observable cleavage or fracture. Colour bright bluish-green.
Found in the Bannat, and at Matlock in Derbyshire. Other localities are mentioned, but they possibly relate to some other Mineral.

Chloride of Copper.

a. ATACAMITE. *Muriate of Copper*, No. 66.
Haüy, 3.484. Phil. 313. Haid. 3.74. Leon. 212.
Occurs in attached crystals; as a green sand at Atacama in Peru; and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 100°. Cleavage parallel to P distinct, less so parallel to M. Fracture uneven. Hard. 3.0, 3.5. Sp.gr. 4.4. Translucent to opaque. Lustre vitreous. Colour green, of various shades, but chiefly dark emerald-green. Streak lighter green.
Massive variety, reniform, with a fibrous structure.
Found principally at Remolinos in Chile.

Native Copper.

a. NATIVE COPPER, No. 8.
Haüy, 3.423. Phil. 296. Haid. 2.444. Leon. 710.
Occurs in variously branched and aggregated crystals, in plates and massive. Primary form a Cube. CRYST. fig. 56. No cleavage. Fracture hackly. Hard. 2.5, 3.0. Sp.gr. 7.7, 8.5. Lustre metallic. Colour red, frequently much tarnished. Streak shining.
Massive varieties, generally amorphous.
Found in Cornwall and in most other Countries, in veins, and occasionally in beds.

Oxide of Copper.

a. RED OXIDE OF COPPER. *Oxydulous Copper.* When earthy, *Tile-ore*, No. 131.
Haüy, 3.462. Phil. 306. Haid. 2.381. Leon. 566 9.
Occurs in attached crystals, and massive, occasionally in thin plates and fibrous.
Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron.

Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 6.0. Transparent, translucent. Lustre adamantine, approaching sometimes to metallic. Colour red of several shades. Streak dull red.

Massive varieties, amorphous. Structure crystalline and amorphous, or botryoidal, with an earthy structure.

Found in most copper mines accompanying other ones of this metal.

Phosphate of Copper.

Right prismatic.

a. LIBETHENITE, No. 495.

Haüy, 3.519. Phil. 314. Haid. 2.166. Leon. 143.

Occurs in small attached octahedral crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 109° 30′. Cleavage parallel to P, distinct; less so parallel to M. Fracture uneven. Hard. 4.0. Sp.gr. 3.6. Transparent, translucent. Lustre resinous. Colour dark green. Streak green.

Found principally at Libethen in Hungary.

Hydrous Phosphate of Copper.

a. RHENITE, No. 496.

Haüy, 3.519. Phil. 315. Haid. 2.173. Leon. 143.

Occurs in attached crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 97° 30′. M,M′ = 37° 30′. Cleavage indistinct, parallel to the horizontal diagonal. Fracture uneven. Hard. 4.5, 5.0. Sp.gr. 4.2. Translucent, opaque. Lustre vitreous. Colour various shades of green, frequently blackish. Streak pale green.

Massive varieties, botryoidal and amorphous. Structure fibrous.

Found near Rheinbreitbach on the Rhine.

Seleniuret of Copper.

a. SELENIURET OF COPPER, No. 53.

Haüy, 3.469. Phil. 304. Haid. 3.150. Leon. 394.

Occurs massive and in thin plates in carbonate of lime at Smaland, Sweden. Soft. Malleable. Lustre metallic. Colour silver-white. Streak shining.

Silicate of Copper.

a. DIOPTASE. *Emerald Copper*, No. 178.

Haüy, 3.477. Phil. 312. Haid. 2.171. Leon. 220.

Occurs in attached crystals.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 126° 17′. Cleavage parallel to P. Fracture uneven. Hard. 5.0. Sp.gr. 3.278. Transparent, translucent. Lustre vitreous. Colour emerald to blackish-green. Streak green.

Found in the Kirghese Steppes, and according to Phillips, at Risbanya in the Bannat.

b. CHRYSOCOLLA. *Copper-green*, No. 179.

Haüy, 3.471. Phil. 312. Haid. 2.158. Leon. 219.

Occurs massive.

No proper crystalline form or cleavage yet observed, but occurring in Siberia and Cornwall in epigene or pseudomorphous crystals, of some of the forms of arseniate, blue carbonate, and red oxide of copper. Hard. 2.0, 3.0. Sp.gr. 2.031. Translucent. Lustre vitreo-resinous. Colour bluish and blackish-green. Streak green.

Several localities are named of this substance, but it is probable that they relate to very different Minerals, some of which appear to be only quartz or calcedony, coloured by carbonate of copper.

Sulphate of Copper.

a. *Soluble*, No. 534.

Haüy, 3.523. Phil. 313. Haid. 2.44. Leon. 111.

Occurs in stalactitic, fibrous, and earthy masses, seldom in crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 95. P,M = 109° 32′. P,T = 128° 27′. M,T = 149° 2′. Cleavage indistinct, parallel to T and M. Fracture conchoidal. Hard. 2.5. Sp.gr. 2.213. Transparent, translucent. Lustre vitreous. Colour bright blue. Streak white.

Found in several copper mines in this and other Countries.

b. BROCHANTITE? No. 515.

An. N.S. 8.241. Haid. 3.81. Leon. 724.

Occurs in minute, thin, rectangular crystals. Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 111° 20′. Cleavage and fracture uncertain. Hard. 3.5, 4.0. Transparent. Lustre vitreous. Colour emerald-green and blackish-green.

Found at Catherinenburg in Siberia, covering mamellated green carbonate of copper.

c. KONIGINE? No. 546.

An. N.S. 11.194.

Primary form a Right rhombic prism, CRYST. fig. 71. M,M′ = 105°. Cleavage perpendicular to axis of prism. Hard. 3.5, 4.0. Translucent Lustre vitreous. Colour emerald-green and blackish-green.

Found at Catherinenburg in Siberia.

Sulphuret of Copper.

a. VITREOUS COPPER, No. 77.

Haüy, 3.454. Phil. 297. Haid. 3.8. Leon. 566, 640.

Occurs in attached hexagonal prisms and massive. Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 71° 30′ nearly. Cleavage parallel to the hexagonal pyramids corresponding to the primary plane. Fracture conchoidal. Hard. 2.5, 3.0. Sp.gr. 5.7. Lustre metallic. Colour lead-grey, frequently tarnished. Streak shining.

Massive varieties, amorphous; structure granular to compact.

Found in Cornwall, finely crystallized, and in most other depositories of copper ore.

Sulphuret of Copper, Iron, &c.

A. FAHLORE. *Grey Copper*, No. 78.

a. *Arsenical.*

Haüy, 3.441. Phil. 300. Haid. 3.1. Leon. 648.

Occurs in attached and imbedded crystals, and massive. Primary form a Cube. CRYST. fig. 56. Predominating form the regular tetrahedron. Cleavage parallel to the planes of the tetrahedron, very indistinct. Fracture conchoidal. Hard. 3.0, 4.0. Sp.gr. 4.8, 5.1. Opaque. Lustre metallic. Colour steel-grey. Streak nearly the same.

Massive varieties, amorphous; structure granular to compact, and sometimes earthy.

Is found accompanying most other copper ores.

b. *Antimonial.*

Differs from the arsenical chiefly in colour, which is much darker. It is also more frequently tarnished on the surface, presenting a remarkable contrast to the relative characters of antimony and arsenic in their native state. The fractured surfaces of antimony retaining their metallic brightness after exposure to the air, while those of arsenic speedily become dull and black.

B. TENNANTITE. No. 79.

Phil. 304. Haid. 3.161. Leon. 604.

Occurs in attached crystals.

Primary form a Cube. CRYST. fig. 56. Cleavage

parallel to the planes of the regular octahedron. Fracture uneven. Hard. exceeding 3.0. Sp.gr. 4.375. Lustre metallic. Colour lead-grey, frequently tarnished on the surface. Streak reddish-grey.

Found in several of the copper mines in Cornwall.

b. PURPLE COPPER. *Buntkupfererz*, No. 80.

Haüy, 3.436. Phil. 299. Haid. 2.467. Leon. 643.

Occurs in attached crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron, indistinct. Fracture uneven. Hard. 3.0. Sp.gr. 5.0. Lustre metallic. Colour purplish and reddish-brown, generally tarnished on the surface. Streak greyish-black.

Massive variety, amorphous. Structure compact.

Found in most copper mines.

A variety of this substance occurs in Cornwall, in the form of thin hexagonal prisms, which are probably pseudomorphous.

Sulphuret of Copper and Iron.

a. COPPER PYRITES. *Yellow Copper*, No. 81.

Haüy, 3.432. Phil. 302. Haid. 2.469. Leon. 644.

Occurs in attached and imbedded crystals, and massive.

Primary form a Square prism. CRYST. fig. 65. $P,e = 117° 15'$. Cleavage parallel to e, fig. 68. Fracture conchoidal. Hard. 3.5, 4.0. Sp.gr. 4.17, 4.3. Lustre metallic. Colour brass-yellow, frequently with a violet and purple tarnish on the surface. Streak greenish-black.

Massive varieties, globular, botryoidal, reniform, stalactitic, and amorphous.

Found in most mines where copper is produced.

b. KUPFERINDIG, No. 83.

Haid. 3.118. Leon. 755.

Occurs in imbedded spheroidal masses, and in flat layers, having an uneven fracture, and a fine granular or earthy structure. Soft. Sp.gr. 3.8. Opaque. Lustre dull resinous. Colour dark blue. Streak shining.

Found in Salzburg and in Thuringia

Silicate and Sulphate of Copper.

a. VELVET COPPER, No. 567.

Haid. 3.168.

Occurs in very short capillary crystals coating the surface of the matrix, and presenting a velvety appearance. Translucent. Lustre pearly. Colour bright blue

Found at Moldawa in the Bannat, and consists of silica, sulphuric acid, and oxides of copper and zinc.

Composition unknown.

a. PELOKONITE, No. 569.

E.N.P.J. 12.134.

Occurs amorphous. No cleavage. Fracture conchoidal. Hard. 3.0. Sp.gr. 2.51, 2.57. Opaque. Lustre vitreous, nearly dull. Colour bluish-black. Streak liver-brown.

Found in the Tierra Amarilla and Remolinos in Chili, accompanying green carbonate of copper. Soluble in muriatic acid, the solution yellowish-green. Not analyzed.

CRYOLITE, No. 514.

Haüy, 2.157. Phil. 197. Haid. 2.66. Leon. 570.

Occurs in single or aggregated crystalline masses.

Primary form not observed. Cleavage parallel to the terminal and lateral planes of a rectangular prism. Fracture uneven. Hard. 2.5, 3.0. Sp gr. 2.963. Translucent, and becomes more transparent after immersion in water. Lustre vitreous, rather pearly on one surface. Colour white, or reddish, or yellowish-brown. Streak white.

Found at Arksut-fiord, West Greenland.

DAVYNE, No. 341.

E.J.S. 7.326. Leon. 433.

Occurs in attached regular hexagonal prismatic crystals with the terminal edges truncated.

Primary form a Rhomboid. CRYST. fig. 106. $P,P' = 112° 16'$. Corresponding nearly, if not exactly, with Nepheline. Cleavage parallel to the planes of the hexagonal prism, distinct. Fracture conchoidal. Hard. 5.0, 5.5. Sp.gr. 2.4. Transparent. Lustre vitreous, pearly upon the cleavage planes. Colour white, sometimes yellowish-brown. Streak white.

Found in cavities, in some of the masses ejected from Vesuvius.

DESMINE, No. 342.

Occurs in small silky tufts accompanying Spinellane from the extinct volcanoes of the Rhine.

DICHROITE. *Iolite. Peliome. Steinheilite*, No. 305.

Haüy, 3.1. Phil. 93. Haid. 2.319. Leon. 466.

Occurs in imbedded crystals, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M' nearly 120°. Cleavage parallel to the lateral planes. Fracture conchoidal. Hard. 7.0, 7.5. Sp.gr. 2.583. Transparent, translucent. Lustre vitreous. Colour blue in the direction of the axis, and yellowish-grey perpendicular to it; sometimes dull yellowish in both directions. Streak white.

Massive varieties, amorphous. Structure indistinctly granular.

Found in Spain, in Bavaria, in Finland, and other localities.

DIPYRE. *Leucolite*, No. 343.

Haüy, 2.596. Phil. 45. Haid. 2 264. Leon. 475.

Occurs in small imbedded crystals.

Primary form not determined. Fracture conchoidal. Hard. 5.0, 5.5. Sp.gr. 2.63. Opaque. Lustre internally vitreous. Colour greyish and reddish-white.

Found in the Western Pyrenees.

DISLUITE, No. 344.

Occurs at Franklin, New Jersey, North America, in regular octahedral crystals imbedded in carbonate of lime.

Colour yellowish-brown. No published description or analysis. Possibly brown Spinelle.

DOMITE, No. 345.

Phil. 203.

Occurs in white, greyish, or yellowish, earthy or pulverulent, amorphous, masses, at Puy de Dome, in Auvergne.

EDINGTONITE, No. 221.

E.J.S. 3.316. Leon. 731.

Occurs in attached crystals in the cavities of Thomsonite.

Primary form, according to Haidinger, a Square prism. CRYST. fig. 65. Cleavage parallel to the lateral planes. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 2.71. Translucent. Lustre vitreous. Colour greyish-white. Streak white

Found in the neighbourhood of Dumbarton, Scotland.

ELAOLITE. *Fettstein. Lythrodes. Sodaite* No. 238.

Haüy, 4.505. Phil. 136. Haid. 3.93. Leon. 468.
Occurs in amorphous masses, with cleavages parallel to the lateral planes, and both the diagonals of a Rhombic prism of 112°. Fracture conchoidal. Hard. 5.5, 6.0. Sp.gr. 2.55, 2.62. Translucent. Lustre vitreo-resinous, sometimes fatty, occasionally opalescent. Colour greenish or bluish-grey, or greyish or brownish-red.
Found in Norway imbedded in Syenite.

EMERALD. *Beryl. Aquamarine*, No. 322.
Hauy, 2.504. Phil. 102. Haid. 2.316. Leon. 391.
Occurs in attached and imbedded crystals and massive.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 104° 28′. Cleavage parallel to all the planes of a regular hexagonal prism, the form it generally assumes. Fracture uneven. Hard. 7.5, 8.0. Sp.gr. 2.68, 2.732. Transparent, translucent. Lustre vitreous. Colour various shades of green, blue, and yellow. Streak white.
Massive varieties, amorphous, structure large granular, or globular with a fibrous structure.
Found in Columbia, Peru, Brazil, North America, Siberia, and in several parts of Europe.

EPIDOTE. *Pistazite. Thallite*, No. 289.
Haüy, 2.568. Phil. 41. Haid. 2.282. Leon. 476.
Occurs in attached and imbedded crystals, massive and granular.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 103° 10′. M,M′ = 63° 25′. Cleavage parallel to P and *h*, fig. 91. Fracture uneven. Hard. 6.0, 7.0. Sp.gr. 3.425, 3.45. Transparent to opaque. Lustre vitreous. Colour various shades of green, greenish-grey, brownish-yellow, and blackish-red. Streak greyish-white.
Massive varieties, amorphous. Structure granular, compact, fibrous. Occasionally arenaceous.
Found in many parts of Europe and America, and in the East Indies.
Thulite and Withamite have been referred to this species.

EPISTILBITE, No. 214.
E.J.S. 4.286. Leon. 735.
Occurs in crystals attached to a mass of the same substance.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 135° 10′. Cleavage parallel to the short diagonal of the prism. Fracture uneven. Hard. 4.5. Sp.gr. 2.25. Transparent, translucent. Lustre vitreous. Colour white. Streak white.
Found in Iceland and the Faroe Islands.

ERLANITE, No. 243.
An. N.S. 8.389. Leon. 736.
Occurs massive and amorphous, forming a bed of 100 fathoms in thickness. Structure granular, compact. Fracture foliated, splintery. Hard. 5.5. Sp.gr. 3.0, 3.1. Opaque. Lustre very feeble. Colour greenish-grey. Streak white, shining.
Found in the Saxon Erzgebirge, near Erla
Used as a flux by iron smelters.

EUCLASE, No. 323.
Haüy, 2.528. Phil. 101. Haid. 2.313. Leon. 395.
Occurs in detached crystals in alluvial ground in Brazil.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 118° 46′. M,M′ = 114° 50′. Cleavage parallel to the terminal plane, and horizontal diagonal, indistinct, but very distinct parallel to the oblique diagonal. Fracture uneven. Hard. 7.5. Sp.gr. 3.098. Transparent. Lustre vitreous. Colour pale bluish-green, blue, and white. Streak white.

EUDYALITE, No. 329.
Phil. 122. Haid. 3.96. E.P.J. 12.81. Leon. 390.
Occurs in imbedded crystals and massive.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 73° 40′. Cleavage parallel to *a*, fig. 107. and to *p*, fig. 121. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 2.9. Faintly translucent, opaque. Lustre vitreous, sometimes dull. Colour brownish-red. Streak white.
Massive varieties, imbedded and amorphous.
Found in Greenland.

FAHLUNITE. *Tricklasite*, No. 265.
Haüy, 3.140. Phil. 56. Haid. 3.97. Leon. 737.
Occurs in imbedded, regular, hexagonal prisms, and in amorphous masses. Cleavage perpendicular to the axis of the prism. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 2.66. Nearly opaque. Colour blackish, yellowish, and greenish-brown. Streak greyish-white.
Found at Fahlun in Sweden.
This has been described as a Right rhombic prism of 109° 28′, and it is said to be cleavable parallel to the lateral planes.

FELSPAR. *Orthose*, No. 226.
Haüy, 3.79. Phil. 113. Haid. 2.251. Leon. 424.
Occurs crystallized and massive.
Primary form an Oblique rhombic prism. P,M = 112° 35′. M,M′ = 118° 58′. Cleavage parallel to the terminal plane and the oblique diagonal, distinct; less so parallel to M and M′. Fracture conchoidal, uneven. Hard. 6.0. Sp.gr. 2.5, 2.6. Transparent, translucent. Lustre vitreous. Colour white, grey, green, red, of different shades. Streak greyish-white.
Massive varieties, amorphous. Structure granular, compact. Sometimes in imbedded globular concretions. But it will probably be found that several distinct Minerals have been classed as compact felspar.
Found in all parts of the World.

FORSTERITE, No. 346.
An. N.S. 7.59. Haid. 3.102. Leon. 739.
Occurs in attached, small, brilliant crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 128° 54′. Cleavage parallel to P. Harder than quartz. Translucent. Lustre vitreous. Colour white.
From Vesuvius, accompanied by Pleonaste and Pyroxene.

FREISLEBEN, No. 347.
Lucas, 2.216.
Is described as having a foliated fracture. Hard. about 3.0. Considerable lustre. Colour blue, sometimes greyish. Soft to the touch. Insoluble in water.
No locality or analysis given.

FUSCITE, No. 348.
Phil. 204. Leon. 474.
Is said by Phillips to be a Rhombic prism of 87° and 93°; is considered by Haidinger to be Pyroxene, and by Leonhard to be Scapolite. It is, therefore, a doubtful species.

Found near Arendahl in Norway.

GABRONITE, No. 232.

Phil. 139.

Occurs crystallized and massive. Primary form a Square prism. CRYST. fig. 65. Cleavage parallel to the lateral planes, indistinct. Fracture uneven. Hard. about 5.0. Sp.gr. 2.9. Opaque. Dull. Colour bluish or greenish-grey, red.

Found only in Norway.

GARNET. Precious, *Almandine*. Black, *Melanite*, *Pyreneite*. Greenish-yellow, *Grossularia*. Yellow, crystallized, *Topazolite*; granular, *Succinite*. Brownish-yellow, granular, *Colophonite*. Greenish, compact, *Allochroite*. Red, *Pyrope*, *Carbuncle*, Reddish-brown, *Essonite*, *Cinnamon-stone*, *Romanzovite*. Magnesian, *Rothoffite*, No. 294—301.

Probably some of these are distinct species, although their crystals are similar in form.

Haüy, 2.213. Phil. 26. Haid. 2.359. Leon. 487.

Occurs in attached and imbedded crystals of the form of rhombic dodecahedrons, granular and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the rhombic dodecahedron, very indistinct. Fracture uneven. Hard. 6.5, 7,5. Sp gr. 3.6, 4.2. Transparent, translucent, rarely opaque. Lustre vitreous, resinous. Colour various shades and combinations of green, yellow, red, brown, black, white. Streak white.

Massive varieties, amorphous, structure granular, compact.

Found in most of the mountainous parts of the World.

GEHLENITE, No. 303.

Haüy, 2.557. Phil. 35. Haid. 3.102. Leon. 212.

Occurs in imbedded and massive aggregations of rectangular, or slightly rhombic crystals.

Primary form uncertain. Cleavage parallel to the planes of a rectangular or rhombic prism. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 3.029. Slightly translucent, opaque. Lustre slightly vitreous, resinous. Colour grey, sometimes yellowish or greenish.

Found only in the valley of Fassa in the Tyrol.

GIESECKITE, No. 264.

Phil. 113. Haid. 3.104. Leon. 461. 464, 465.

Occurs in imbedded crystals in the form of hexagonal prisms.

Structure of the crystals granular. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 2.832. Opaque. Lustre slightly resinous. Colour brownish-grey and greenish. Streak white.

Found in Greenland by Sir Charles Giesecké.

GIGANTOLITE, No. 349.

A name given by Nordenskiold, on account of the size of the crystals, to a Mineral occurring in Finland, but first found at Schneeberg in Saxony, and then called Pinite. The Saxon specimens are decomposed, soft, and dull red. The Finland Mineral is not decomposed, and is dull dark green. Both varieties present the form of imperfect hexagonal prisms, and may be split into thin plates. The same substance has been found in North America, and named Phyllite.

GLAUCOLITE, No. 244.

P.M. and An. 2.463. Leon. 742.

Occurs massive. Structure crystalline. Cleavage parallel to the planes of a Rhombic prism, of about 107° or 143° 30′, indistinct. Fracture uneven. Hard. 5.0, 6.0. Sp gr. 2.7, 3.2. Translucent. Lustre vitreous. Colour lavender-blue, green. Streak lighter.

Found near the lake Baikal in Siberia.

This Mineral affords an instance of the disadvantage of significant names, as at least three different substances have been so called, merely on account of their colour, one of which, from Norway, has a cleavage parallel to the planes of the rhombic dodecahedron, and another has no apparent cleavage.

GMELINITE. *Hydrolite*, De Drée, No. 211.

Haüy, 3.177. Haid. 3.104. Leon. 742.

Occurs in attached crystals of the form of hexagonal prisms, lining cavities in trap rocks.

Primary form a Rhomboid. CRYST. fig. 106. Cleavage parallel to the primary planes. Fracture uneven. Hard. 4.5. Sp.gr. 2.05. Translucent. Lustre vitreous. Colour white, and pale dull yellow and red. Streak white.

Found in the Vicenti, in Ireland, and in North America.

GOLD.

a. NATIVE GOLD, No. 17.

Haüy, 3.235. Phil. 322. Haid. 2.436. Leon. 707.

Occurs only in a metallic state, crystallized, and massive.

Primary form a Cube. CRYST. fig. 56. No cleavage. Fracture hackly. Hard. 2.5, 3.0. Sp.gr. 14.857. Opaque. Lustre metallic. Colour yellow, of several shades. Streak shining.

Found in North America, Mexico, Brazil, Peru, and other parts of South America, and in several parts of Europe, Asia. and Africa.

Native Gold is usually alloyed with a small quantity of silver. When the proportion is considerable the compound passes under the name of

b. ELECTRUM, No. 18.

GREEN EARTH, *Talc Zographique*, No. 257.

Haüy, 2.493. Phil. 117. Haid. 2.193. Leon. 189.

Occurs massive, imbedded in or lining the cavities of trap rocks. Fracture earthy. Hard. 1.0, 1.5. Sp gr. 2.631. Opaque. Dull. Colour greyish, bluish, blackish-green. Streak shining.

Found in the Faro Islands, and in several parts of Europe, particularly near Verona, and generally wherever amygdaloidal rocks occur.

Several apparently different substances are so named on account of their colour and earthy fracture. Crystals of a green earthy substance of the form of Pyroxene are occasionally found in trap rocks.

HARMOTOME. *Andreolite*. *Ercinite*, No. 220.

Haüy 3.142. Phil. 56. Haid. 2.229. Leon. 196.

Occurs in attached crystals, generally intersecting each other lengthwise.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′= 110°; Levy. Cleavage parallel to the primary planes, and to both the diagonals of the prism. Fracture uneven. Hard. 4.5. Sp.gr. 2.35, 2.39. Transparent, translucent. Lustre vitreous, sometimes pearly. Colour greyish, yellowish, reddish-white. Streak white.

Found in Scotland, and in several places on the Continent of Europe.

The crossed crystals most commonly met with are

from Andreasberg, and the simple ones from Strontian in Scotland.

HARRINGTONITE, No. 350.

A white substance so named from Ireland. It occurs in thin tabular masses, with a fine granular structure, and may possibly be only a variety of some known Mineral.

HAÜYNE. *Latialite*, No. 565.

Haüy, 2.335. Phil. 374. Haid. 3.107. Leon. 459.

Occurs in attached dodecahedral crystals, granular, and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the diagonal planes of the cube, indistinct. Fracture uneven. Hard. 5.5, 6.0. Sp gr. 2.68. Transparent to opaque. Lustre vitreous. Colour blue, sometimes greenish, white. Streak white.

Massive varieties, amorphous, structure granular, compact.

Found in the cavities of ancient lavas, and in the fragments of rocks ejected from Vesuvius.

HEDENBERGITE, No. 351.

Haüy, 4.495. Phil. 66. Leon. 506.

Is said by Phillips to measure the same as *Amphibole;* by Levy to be *Pyroxene;* by Berzelius to cleave into *obtuse rhomboids*, similar to that of *carbonate of lime;* and by Haüy, into *octagonal prisms* with a base oblique to the axis. It is uncertain, therefore, to what Mineral the published descriptions really apply.

HELVIN, No. 302.

Haüy, 2.333. Phil. 244. Haid. 2.357. Leon. 462.

Occurs in attached and imbedded tetrahedral or octahedral crystals.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron, indistinct. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 3.166. Translucent. Lustre vitreo-resinous. Colour dull yellow, sometimes brownish. Streak white.

Found at Schwarzenberg in Saxony.

HERDERITE, No. 352.

P.M. and An. 4 1.

Occurs in imbedded crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 115° 53′. Cleavage parallel to the lateral planes, and to the long diagonal of the prism. Fracture small conchoidal. Hard. 5.0. Sp gr. 2.985. Nearly transparent. Lustre vitreous, slightly inclined to resinous. Colour yellowish and greyish-white. Streak white.

Found imbedded in Fluor at Ehrenfriedersdorf in Saxony.

HERSCHELITE, No. 353.

An. N.S. 10.361. Leon. 745.

Occurs in attached hexagonal crystals in the cavities of granular olivine.

Primary form a Rhomboid. CRYST. fig. 106. P,*a* about 132°. No perceptible cleavage. Fracture conchoidal. Hard. about 4.0. Sp.gr. 2 11. Translucent. Opaque. Colour white.

Found at Aci Reale in Sicily.

HEULANDITE. *Haydenite*, No. 215.

Haüy, 3.155. Phil. 38. Haid. 2.242. Leon. 745.

Occurs in attached crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 108° 1′. M,M′ = 97° 39′. Cleavage parallel to the oblique diagonal of the prism, very distinct. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 2.2. Transparent, translucent. Lustre vitreous, on the cleavage planes pearly. Colour white, grey, yellow, red, brown. Streak white.

Massive varieties, granular.

Found principally in Iceland and the Faroe Islands, and generally lining cavities in trap rocks.

HISINGERITE, No. 172.

Phil. 204. Haid. 3.108. Leon. 212, 746.

Occurs massive, with a distinct cleavage in only one direction, and an earthy fracture. Soft. Sp.gr. 3.045. Opaque. Colour black. Streak greenish-grey.

Found in Svärta Parish, Sudermanland.

HUMITE, No. 354.

Bour. Cat. 52. Phil. 205. Haid. 3.110. Leon. 747.

Occurs in attached crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 120°. Cleavage parallel to M and M′ distinct and bright. Fracture uneven. Hard. 6.5, 7.0. Transparent, translucent. Lustre vitreous. Colour brownish-yellow and light reddish-brown. Streak white.

Found on Monte Somma.

HYALOSIDERITE, No. 284.

Haid. 3.111. Leon. 533.

Occurs in imbedded crystals in a brown basaltic amygdaloidal rock.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 105°; W.P. Cleavage parallel to P. Fracture uneven, Hard. 5.5. Sp.gr. 2.875. Translucent, opaque. Lustre vitreous, superficially metallic. Colour reddish-brown. Streak light brown.

Found at Kaiserstuhl in Brisgaw.

The form and measurements of this Mineral agree very nearly with those of Olivine.

HYPERSTHENE. *Diallage metalloide*, var. *Labrador Hornblende*. *Paulite*, No. 285.

Haüy, 2.417. Phil. 70. Haid. 2.209. Leon. 516.

Occurs in crystalline masses, sometimes presenting parts of the natural surfaces of crystals. Cleavage parallel to the lateral planes of a rhombic prism of 93° 30′, and to both diagonals. Fracture uneven. Hard. 6.0. Sp.gr. 3.389. Opaque. Lustre metallic in one direction, on the cross fracture, vitreous. Colour on the metallic looking surface reddish, in other directions greyish or greenish-black. Streak greenish-grey.

Massive varieties, amorphous.

Found at Labrador, and in the Island of St. Paul.

This and the Bronzite and Schiller spar have the same cleavages and measurements.

JADE. *Igida*, its Indian name. *Axe stone*. *Beilstein*. *Nephrite?* *Saussurite?* No. 306.

Haüy, 4.498. Phil. 134. Haid. 3.149. Leon. 422.

There is much uncertainty and confusion in the published description of Jade, Nephrite, and Saussurite; and it is not apparent what the Mineral is to which the name Igida has been applied in India. The Axe stone of the South Sea Islands appears to be a compact amianthus, or a serpentine enveloping a considerable quantity of amianthus. Werner's Jade or Beilstein is a brittle, yellowish-brown, fibrous Mineral. It is probable that the Chinese Jade is the substance which is also named Yu, and is believed to be Prehnite.

a. NEPHRITE, No. 307. This has been described as follows.

Haüy, 4.498. Phil. 134. Haid. 3.131. Leon. 764.

Occurs massive. Structure *fibrous*, compact. Fracture splintery. Hard. 7.0. Sp.gr. 2.9, 3.02. Translucent, opaque. Colour green of several shades. Very tough.

Found in China, Egypt, and the Islands in the South Seas, where it is cut by the natives into various forms.

b. SAUSSURITE, No. 308. This, which has been called by Haüy *Felspath tenace*, has also received the names *Jade*, *Axe stone*, &c. as synonyms, and is described as follows.

Haüy, 3.95. Phil. 135. Haid. 3.148. Leon. 422.

Occurs massive. Structure *foliated*, granular. Cleavage parallel to the planes of a Rhombic prism of about 124°; Haid. Fracture splintery. Hard. 5.5. Sp.gr. 2.25, 3.35. Nearly opaque. Lustre pearly. Colour greenish and greyish-white. Streak white.

Found in Corsica, Stiria, and some other places.

A more precise examination of these Minerals, and more distinct descriptions and analyses are necessary to a correct separation of the several varieties into more definite species. Specimens occur in Mineral cabinets under some or all of these names, which do not agree with any of the published descriptions.

IBERITE, No. 355.

An. 3.152.

Occurs in attached slender, four-sided prisms, with terminal faces obliquely truncated, and massive with a radiated structure.

Primary form not sufficiently described, and no measurements given. Cleavage parallel to the axis of the prism in two directions. Fracture uneven. Very soft. Translucent on the edges of the crystals. External lustre nearly dull, internal vitreous. Colour white. Adheres slightly to the tongue.

Found near Teflis in Georgia.

Is perhaps Laumonite, or one of the already known members of the family of Zeolites, in a state of partial decomposition.

IDOCRASE. *Vesuvian. Wiluite. Egeran.* Red, *Frugardite.* Greenish-yellow, *Loboite.* Blue, *Cyprine.* No. 291 to 293.

Haüy, 2.544. Phil. 33. Haid. 2.354. Leon. 483, 484.

Occurs in attached and imbedded crystals, and massive.

Primary form a Square prism. CRYST. fig. 65. Cleavage parallel to the primary planes, distinct, and less so parallel to the diagonals of the prism. Fracture uneven. Hard. 6 5. Sp.gr. 3.08, 3.4. Transparent, translucent. Lustre vitreo-resinous. Colour several shades of grey, blue, green, yellow, brown, black. Streak white.

Massive varieties, amorphous. Structure fibrous, granular, compact.

Found originally in the neighbourhood of Vesuvius, and since in many parts of Europe, and in Asia and America.

JEFFERSONITE, No. 273.

Haid. 3.115. Leon. 505, 506.

Has the form, measurements, and most other characters of Pyroxene.

Found near Sparta, New Jersey, North America.

ILMENITE, No. 356.

P.M. and An. 10.187. E.P J. N.S. 3.187, 386.

Occurs in imbedded crystals in Cleavelandite.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 136° 30′. No cleavage observed. Fracture uneven. Hard. 5.0. Sp.gr. 5.43. Opaque. Lustre vitreous. Colour black.

Found near Lake Ilmen in Siberia.

INDIANITE, No. 315.

Phil. 44. Haid. 3.113. Leon. 748.

Occurs in granular masses. Part of a fragment at the British Museum having afforded a measurement of 95° 15′ on cleavage planes. Hard. 5.0, 5.5 Sp.gr. 2.74. Bournon. Translucent. Colour nearly white.

Found in the Carnatic in India.

IRIDIUM.

a. OSMIURET OF IRIDIUM, No. 16.

Haüy, 3.234. Phil. 326. Haid. 3.114. Leon. 701.

Occurs in loose hexagonal crystals, and flattened grains, accompanying native platina.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ not ascertained. Cleavage perpendicular to the axis, very distinct. Hard. 4.5, 5.0. Sp.gr. 19.5. Opaque. Lustre metallic. Colour pale steel-grey.

Found in South America and in the Uralian mountains.

IRON.

Aluminate of Iron?

a. SKORIAN, No. 149.

Breit. 88.

Occurs in amorphous masses, resembling a slag or scoria.

Primary form apparently a Rhombic prism. Cleavage uneven. Fracture conchoidal, uneven. Hard. 8.0, 8.5. Sp.gr. 3.7, 3.8. Lustre vitreous. Colour black.

Found at Bischoffstein in Bavaria and at Schandau in Saxony.

Cubic Arseniate of Iron.

a. PHARMAKOSIDERIT, No. 469.

Haüy 4.135. Phil. 211. Haid. 2.162. Leon. 165.

Occurs in attached crystals, and sometimes massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the primary planes, indistinct. Fracture uneven. Hard. 2.5. Sp.gr. 3.0. Transparent, translucent, opaque. Lustre vitreous. Colour green of several shades, yellowish-red, yellowish and greenish-brown. Streak a paler colour.

Massive variety, amorphous, structure granular.

Found principally in Cornwall, also at St. Leonhard in France, at Schwartzenberg in Saxony, and at Franklin, North America.

Rhombic Arseniate of Iron.

a. SKORODITE. *Martial Arseniate of Copper* of Bournon, No. 468.

Phil. 320, 321. Haid. 3.149. Leon. 166.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′= 120° 10′. Phil. Cleavage parallel to the primary planes, indistinct. Fracture uneven. Hard. 3.5, 4 0. Sp.gr. 3.16, 3.2. Transparent, translucent, opaque. Lustre vitreous, brighter on the natural than the fractured surfaces. Colour bluish and blackish-green, brown, black. Streak white.

Massive varieties, globular, structure fibrous, radiating.

Found in Cornwall, Saxony, Carinthia, and in more perfect crystals in Brazil.

Berzelius seems to consider the variety from Brazil as a distinct species, but as it agrees in measurement with the others, it is probable that the analysis of more perfect specimens would lead to a different conclusion.

Arseniate of Iron?

a. Pittizite. *Iron pitch ore? Iron sinter?* No. 470.

Phil. 236. Haid. 3.115. Leon. 128.

Occurs in reniform and stalactitic masses. Structure compact. Fracture conchoidal. Soft. Sp.gr. 2.4. Translucent, opaque. Lustre vitreous. Colour brown of different shades.

Found in Saxony and Silesia.

An uncertain species, and probably comprehending several distinct Minerals, as specimens have been received in this Country under these names, differing from each other in all their physical characters.

b. Arsenite of Iron? No. 471.

Brit. Min. 5 275.

Described by Gregor as massive, compact to earthy. Lustre dull waxy. Colour dull bluish-olive-green.

Found in Cornwall.

Carbonate of Iron.

a. Carbonate of Iron. *Brown Spar. Sphathose Iron. Sphdrosederit*, when botryoidal or globular, No. 452.

Haüy, 4.113. Phil. 236. Haid. 2.102. Leon. 296,7.

Occurs in attached crystals and massive.

Primary form a Rhomboid. Cryst. fig. 106. P,P′ = 107°. Cleavage parallel to the primary planes, distinct. Fracture imperfect conchoidal. Hard. 3.5, 4.5. Sp.gr. 3.6, 3.829. Transparent, translucent, opaque. Lustre vitreous, inclining to pearly. Colour white, yellowish, and greenish-grey, yellow, red, and brown of different shades.

Massive varieties, tabular. Structure fibrous, the direction of the fibres nearly perpendicular to the flat surfaces; botryoidal and globular, structure fibrous, diverging; amorphous structure, foliated, granular, compact.

Found in Cornwall, Scotland, and Ireland, and in many metalliferous veins in other parts of Europe and in America.

Argillaceous Carbonate of Iron.

a. Clay Iron Stone, No. 453.

Haid. 2.408. Phil. 237. Leon. 235,6; 550,1.

The different clay iron stones appear to be carbonates of iron mixed with different proportions of silex, clay, and other foreign matters.

Carburet of Iron.

a. Graphite. *Black Lead. Plumbago*, No. 42.

Haüy, 4 85. Phil. 364. Haid. 2.191. Leon. 674.

Occurs in imbedded crystals of the form of regular hexagonal prisms, and massive. Primary form a Rhomboid. Cryst. fig. 106. P,P′ unknown. Cleavage parallel to the terminal planes of the prisms, very distinct, and the laminæ flexible. Fracture uneven. Hard. 1.0, 2.0. Sp.gr. 1.8, 2.1. Opaque. Lustre metallic. Colour iron or steel-grey, or blackish-grey. Streak black, shining.

Massive varieties, in irregular nodules and amorphous. Structure foliated, granular, compact.

Found in various parts of Europe and America, and appears to be intimately related to Anthracite.

The finest kind found in this Country occurs at Borradaile, in Cumberland.

The difference of composition between the foliated and granular varieties does not appear to have been ascertained.

b. Siderographite, No. 43.

Sill. 2.176. Leon. 716.

Resembles laminated plumbago. Sp.gr. 5.114. Magnetic. Consists of metallic iron and plumbago.

Found at Schooley's Mountain, New Jersey, North America.

Chromate of Iron.

a. Chromate of Iron, No. 420.

Haüy, 4.130. Phil. 210. Haid. 2.396. Leon. 557.

Occurs in imbedded octahedral crystals and grains, and massive. Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the planes of the regular octahedron. Fracture uneven. Hard. 5.5. Sp.gr. 4.0, 5.0. Opaque. Lustre imperfect metallic. Colour dark brown, black. Streak brown.

Massive varieties, amorphous. Structure granular, the grains sometimes separated by their partitions of talc coloured by chromic acid; compact.

Found in Scotland, in the Shetland Islands of Unst and Fetlar; in France, and other parts of Europe; in Siberia, and near Baltimore, at Hoboken, New Jersey, and some other places in North America.

Native Iron.

a. Meteoric?

Aerolite. *Meteorite*, No. 1.

Haüy, 3 531. Phil. 213. Haid. 2.442. Leon. 713.

Occurs disseminated in aerolites or meteoric stones, and in compact and vesicular masses, the cavities being sometimes filled with compact olivine. It is also said to have occurred crystallized in the form of the regular octahedron.

Primary form a Cube. Cryst. fig. 56. No apparent cleavage. Fracture hackly. Hard. 4.5. Sp.gr. 6.48, 7.768. Opaque. Lustre metallic. Colour pale steel-grey. Streak the same, shining.

Found in meteoric stones in various parts of the World. In compact and vesicular masses in Siberia, Peru, Mexico, North America, the Cape of Good Hope, and in several parts of Europe. Knives of meteoric iron were found in possession of some of the Esquimaux Tribes in North America.

b. Terrestrial Native Iron, No. 2.

Haüy, 3.531. Phil. 213. Haid. 2.442. Leon. 715.

Occurs massive in thin plates, ramose or cellular, sometimes covered by brown oxide of iron. Lustre metallic. Colour lighter than common iron.

Found near Grenoble in France, and at Steinbach, Eibestock, and Hamsdorf in Saxony.

S.J. 12.155. No. 3.

Occurs as a thin stratum, in a mass of mica slate, coated with crystalline graphite. Cleavage uncertain. Hardness the same as metallic iron. Sp.gr. 5.95, 6.72. Colour less silvery-white than meteoric iron. Malleable.

Found at Canaan, Connecticut, United States. Not alloyed with any other metal.

c. Terrestrial Native Iron containing Arsenic, No. 4.

S.J. 14.183. Leon. 663

Cleavage parallel to planes inclining to each other at about 120°. Fracture hackly. Hardness nearly that of ordinary steel. Sp.gr. 7.337. Lustre of

the cleavage planes highly metallic. Colour greyish, silver-white. Malleable.

Found in Bedford County, Pennsylvania, United States.

d. Volcanic Native Iron, No. 5.

Phil. 214.

Found in the Department of Puy de Dome in France, in a ravine formed by torrents across the lava and scoriæ of the mountain of Graveneire.

e. Terrestrial Native Steel? No. 6.

S.J. 12.155.

Found with the native iron at Canaan, Connecticut, in small angular fragments. Structure granular. Scratches glass. Colour silvery white. Brittle.

f. Volcanic Native Steel? No. 7.

Phil. 214.

Found near La Bouiche, in the Department of Allier, France, near a coal mine which appeared to have undergone spontaneous combustion.

Oxalate of Iron.

a. Humboldtine, No. 591.

Haüy, 4.139. Phil. 242. Haid. 3.110, Leon. 789.

Occurs crystalline and massive. Primary form not ascertained. Soft. Sp.gr. 1.3. Opaque. Dull. Colour brightish yellow.

Massive variety, small, flattish, reniform pieces. Structure fine earthy.

Found near Bilin in Bohemia.

Oxydulous Iron.

a. Magnetic Iron, No. 126.

Haüy, 3.560. Phil. 221. Haid. 2.399. Leon. 554.

Occurs in attached and imbedded crystals, arenaceous and massive.

Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the planes of the regular octahedron, distinct, but in some varieties not obtainable. Fracture conchoidal, uneven. Hard. 5.5, 6.5. Sp.gr. 4.4, 5.1. Opaque. Lustre metallic, occasionally bright. Colour iron-black. Streak black.

Massive varieties, amorphous. Structure granular to compact.

Found in several parts of North and South America and Europe, and in the East Indies and China.

Titanium is frequently contained in magnetic iron, but the varieties containing it have not hitherto been well distinguished.

Oxide of Iron.

a. Crystallized and retaining the metallic lustre.

Oligiste Iron. *Specular Iron. Micaceous Iron*, No. 125.

Haüy, 4.5. Phil. 224. Haid. 2.404. Leon. 545.

Occurs in attached crystals and massive.

Primary form a Rhomboid. Cryst. fig. 106. P,P′= 86° 10′. Cleavage parallel to the primary planes, and perpendicular to the axis. Fracture uneven, conchoidal. Hard. 5.5, 6.5. Sp.gr. 5.0, 5.251. Opaque. Lustre metallic. Colour deep steel-grey to iron-black, frequently with a brilliant iridescent tarnish on the surface. Streak red, and reddish-brown. Slightly magnetic.

Massive varieties, amorphous, structure foliated.

Found in the Isle of Elba, and in many other parts of Europe. It also occurs in the lava of Auvergne in France, and in that of Vesuvius.

b. Crystallized, but without metallic lustre, the crystals being very minute and thin, and frequently transparent

Goethite. *Pyrosiderite. Iron Froth.*

The first of these varieties occurs in very thin, transparent, crystalline plates, in the cavities of black Hematite. The iron froth consists of very thin, brownish-red, scaly particles, which are slightly coherent, with a greasy feel, and staining the fingers.

It is found plentifully in Devonshire and Lancashire, and generally accompanies other varieties of this species.

c. Fibrous, compact, and earthy masses.

Red Hematite.

Leon. 548.

1. Occurs in globular and botryoidal shapes. Structure fibrous, generally radiating. Sp.gr. 4.7, 5.0. Opaque. Sometimes with a metallic lustre externally; sometimes dull. Internally nearly dull. Colour externally bluish-grey, greyish-red, red; internally red. Streak red.

Found at Ulverstone in Lancashire, in considerable quantities, and in other parts of Great Britain and Europe.

2. Amorphous masses. Structure compact, and sometimes slaty. Sp gr. 3.5, 5.0. Fracture conchoidal. Lustre and colour nearly the same as the preceding variety.

3. Red ochre. Red clay-iron-stone, generally found in compact and earthy masses. The distinguishing character is the shining *red* stain they produce on the fingers.

Oxide of Iron, Zinc, and Manganese.

a. Franklinite, No. 127.

Phil. 226. Haid. 2.403. Leon. 551.

Occurs in attached crystals, granular and massive.

Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the planes of the regular octahedron, very indistinct. Fracture conchoidal. Hard. 6.0, 6.5. Sp.gr. 4.87, 5.09. Opaque. Lustre metallic. Colour iron-black. Streak deep red-brown. Magnetic without polarity.

Massive varieties, amorphous. Structure granular, compact.

Found at Franklin, New Jersey, North America.

Oxide of Iron and Lead.

a. Beudantite, No. 136

An. N.S 11.195. Leon. 722.

Occurs in small aggregated crystals.

Primary form a Rhomboid, Cryst. fig. 106. P,P′= 92° 30′. Cleavage perpendicular to the axis. Hard. 4.0, 5.0. Nearly opaque. Lustre resinous. Colour black; in thin fragments deep brown. Powder greenish-grey.

Found at Horhausen on the Rhine.

Nepheline has also been named Beudantite.

Hydrate of Iron.

a. Hydrous Oxide of Iron. *Brown Iron-ore. Stilpnosiderite?* No. 143.

Haüy, 4.101. Phil. 226. 230. Haid. 2.411. Leon. 230.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. Cryst. fig. 71. M,M′ = 95° 14′. Levy. Cleavage parallel to the short diagonal. Fracture uncertain. Hard. 5.0, 5.5. Sp.gr. 3.93. Nearly opaque. Lustre adamantine. Colour brown, of various shades. Streak yellowish-brown.

Massive varieties. Brown hematite, globular, reniform, and some of the varieties of brown and yellow clay-iron-stone. Stalactitic, structure fibrous, or fibro-

laminar. Sometimes in pseudomorphous crystals.

Found in good crystals in Cornwall, and the other varieties in most parts of the World.

Oxide of Iron and Manganese?

a. UMBER, No. 128.

Phil. 232. Haid. 3.186.

Occurs massive, amorphous. Structure earthy. Fracture conchoidal. Soft. Sp gr. 2.2. Opaque. Dull. Colour yellowish and reddish-brown.

Found in the Isle of Cyprus.

Phosphate of Iron.

a. VIVIANITE, *Blue Iron*, No. 488.

Haüy, 4 126. Phil 238. Haid. 2.188. Leon. 137, 284.

Occurs in attached crystals, in imbedded crystalline aggregations, and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 105° 19′. M,M′ = 108°. Levy. Cleavage parallel to the oblique diagonal. Fracture indistinct. Hard. 1.5, 2.0. Sp.gr. 2.66, 2.70. Transparent, translucent. Lustre vitreous. Colour various shades of blue and green. Streak lighter colour.

Massive varieties, aggregations of crystalline particles, or globular and amorphous earthy masses.

Found crystallized in Cornwall, at Bodenmais in Bavaria, in Brazil, in New Jersey, North America, and in some other places.

The compact earthy varieties occur in several parts of Europe and America.

b. KARPHOSIDERITE? No. 489.

E J.S. 8.181.

Occurs in reniform masses. Structure granular, compact. Hard. 4 0, 4 5. Sp.gr. 2.5. Opaque. Lustre resinous. Colour pale and bright straw-yellow. Streak the same. Shining. Feels greasy. Much resembles iron sinter.

Found in Greenland.

Scheelate of Iron and Manganese.

a. WOLFRAM, No. 414.

Haüy, 4.366. Phil. 255. Haid. 2.387. Leon. 313.

Occurs in attached and imbedded crystals, massive, and pseudomorphous.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M′ = 110°. 50′. M,M′ = 101° 5′. Cleavage parallel to the terminal plane and to both its diagonals, that through the oblique diagonal very distinct. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 7.1, 7.3. Opaque. Lustre imperfect metallic. Colour dark brown, brownish-black. Streak dark brown.

Massive varieties, amorphous, structure crystalline, columnar. The pseudomorphous crystals are octahedrons resembling those of Scheelate of lime.

Found very generally in tin mines, and in other veins in primitive rocks.

Silicate of Iron.

a. CRONSTEDTITE, No. 281.

Phil. 227. Haid. 3.90. Leon. 211.

Occurs in small, thin, attached hexagonal prisms, sometimes in radiating groups, and massive. Primary form a Rhomboid. CRYST. fig. 106. Cleavage perpendicular to the axis, distinct. Hard. 2.0, 2.5. Sp.gr. 3.348. Opaque. Lustre vitreous. Colour black and brownish-black. Streak dull green.

Massive variety, reniform. Structure fibrous.

Found near Przibram in Bohemia, and in Cornwall.

b. SIDEROSCHISOLITE, No. 175.

E.J.S. 2.371. Leon. 778.

Occurs in small three-sided and six-sided pyramids attached by their apex. Cleavage parallel to the base of the pyramids. The face of cleavage smooth, the planes of the pyramids convex. Hard. 2.0, 3.0. Sp.gr. *probably* above 3.0.

Supposed to be a variety of Cronstedtite by Dr. Wernekingk, but the description is too imperfect for an exact comparison.

Found at Conhonas do Campo, Brazil.

c. THRAULITE, No. 176.

E J.S. N.S. 1.185.

Occurs in amorphous masses, accompanying iron pyrites, at Bodenmais, in Bavaria. Structure curved, foliated. Cross fracture uneven. Nearly opaque. Lustre vitreo-resinous. Colour brownish-black.

d. NONTRONITE, No. 177.

E.J.S. 10.150.

Occurs in small nodules imbedded in an ore of manganese. Fracture earthy. Opaque. Dull. Colour pale yellow, sometimes greenish. Streak shining. Unctuous to the touch and very tender.

Found near the village of St. Pardoux, Arrondissement of Nontron, Department of Dordogne, France.

e. CHLOROPAL, No. 174.

Phil. 378. Haid. 3.85. Leon. 179.

Occurs massive, amorphous. Structure compact, sometimes earthy. Fracture conchoidal, uneven. Hard. 3.0, 4.0. Sp.gr. 1.8, 2.0. Opaque. Lustre of the compact variety dull resinous. Colour green, sometimes reddish-brown.

Found near Unghwar, in Hungary.

f. GREEN IRON-EARTH? No. 357.

Haid. 3.106. Leon. 237.

Occurs reniform, botryoidal, globular, and amorphous. Surface smooth. Structure *thin fibrous*, curved lamellar, compact, sometimes pulverulent. Lustre resinous. Colour green, of several shades. Streak yellowish-grey.

Found at Schneeberg, in Saxony, and is a very imperfectly determined species.

The specimens which have appeared in this Country as green iron-earth are yellowish-green, with a fine granular fracture.

Silicate of Iron and Lime.

a. YENITE. *Ilvaite*, No. 280.

Haüy, 4.91. Phil. 24. Haid. 2.414. Leon. 528.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 61. M,M′ = 111° 30′. Cleavage parallel to the long diagonal of the prism. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 3.8, 4.0. Opaque. Lustre vitreous. Colour black, sometimes brownish or greenish. Streak the same.

Massive varieties, amorphous, structure columnar, compact.

Found principally at Rio la Marina, and Cape Calamita in the Isle of Elba, and in Silesia, Norway, Siberia, and North America.

Sulphate of Iron.

a. MELANTERITE. *Green vitriol*, No. 540.

Haüy, 4.140. Phil. 240. Haid. 2.41. Leon. 112.

Occurs in attached crystals, massive, fibrous, and earthy, resulting from the decomposition of other Minerals.

Primary form an Oblique rhombic prism, P,M = 99°

20′. M,M′ = 82° 20′. Cleavage parallel to all the primary planes. Fracture conchoidal. Hard. 2.0. Sp.gr. 1.832. Transparent, translucent. Lustre vitreous. Colour green, of several shades, yellow, and yellowish-brown. Streak white. Taste sweetish and astringent.

Massive varieties, amorphous, structure granular, botryoidal, reniform, stalactitic. Structure fibrous; in thin fibres, filling the fissures of decomposing shale.

Found in most mines in which sulphuret of iron occurs, and is frequently produced on the surface of cabinet specimens. It is also found in coal mines.

Red Sulphate of Iron?

a. BOTRYOGENE, No. 541.

E.J.S. 9.48.

Occurs in attached and aggregated crystals, the aggregations forming globular, botryoidal, and reniform shapes, with a crystalline surface.

Primary form an Oblique rhombic prism, P,M = 113° 37′. M,M′ = 119° 56′. Cleavage parallel to M,M′, distinct, and indistinct parallel to another prism of 81° 44′. Hard. 2.25, 2.5. Sp.gr. 2.039. Translucent. Lustre vitreous. Colour deep yellowish-red, yellow. Streak yellow. Less soluble than green sulphate.

Found in the great copper mine at Fahlun in Sweden.

Persulphate of Iron?

a. MISY, No. 543.

E.J.S. 9.51.

Occurs in the form of a yellow crystalline powder at Fahlun in Sweden, and at Goslar in the Hartz.

Cubic Sulphuret of Iron.

a. IRON PYRITES, No. 72.

Haüy, 4.38. Phil. 217. Haid. 2.457. Leon. 657.

Occurs in attached and imbedded crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the primary planes, distinct, less so parallel to the planes of the regular octahedron. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 4.60, 5.03. Opaque. Lustre metallic. Colour brass-yellow. Streak brownish-black.

Massive varieties, amorphous; structure granular, compact. Globular, and stalactitic; the surface drusy; structure fibrous or columnar, radiating. Occasionally in separate fibres.

Found in most parts of the World, and in some mining districts in great abundance.

It sometimes contains gold; and in Sweden, Bohemia, and Anglesey in this Country a pale yellow variety occurs in granular masses, containing selenium.

Prismatic Sulphuret of Iron

a. WHITE IRON PYRITES, No. 73.

Haüy, 4.68. Phil. 220. Haid. 2.462. Leon. 660.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 106° 2′ Cleavage parallel to M and M′, distinct. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 4.678. Opaque. Lustre metallic. Colour pale whitish, greenish, or greyish-yellow. Streak greyish-black.

Massive varieties, botryoidal, reniform, stalactitic, and amorphous. Surface drusy. Structure diverging, fibrous, or columnar.

Found in most mining districts.

Magnetic Sulphuret of Iron.

a. MAGNETIC IRON PYRITES, No. 74.

Haüy, 4.64. Phil. 221. Haid. 2.465. Leon. 665.

Occurs in imbedded hexagonal crystals, and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ not ascertained. Cleavage parallel to all the planes of a regular hexagonal prism. Fracture uneven. Hard. 3.5, 4.5. Sp.gr. 4.631. Opaque. Lustre metallic. Colour pale yellowish and brownish-red. Liable to tarnish. Streak greyish-black.

Massive varieties, amorphous. Structure foliated, granular, compact.

Found crystallized, accompanying native silver in Norway and the Hartz. Massive in Cornwall, Wales, North America, Bavaria, Saxony, and many other places.

Sulpho-arseniuret of Iron.

a. MISPICKEL. *Arsenical Iron*, No. 111.

Haüy, 4.28. Phil. 215. Haid. 2.448. Leon. 663.

Occurs in attached or imbedded crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 111° 12′. Cleavage parallel to the primary planes. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 6.127. Opaque. Lustre metallic. Colour tin-white, sometimes with a yellowish tarnish. Streak greyish-black.

Massive varieties, amorphous. Structure columnar, granular, compact.

Found in most metallic veins in the older rocks.

Sulphuret of Iron and Arsenic.

a. HÜTTENBERGITE. *Axotomous Arsenical Pyrites*, No. 112.

Haid. 2.448.

Occurs crystalline and massive.

Primary form a Right rhombic prism, CRYST. fig. 71. M,M′ = 122° 26′. Cleavage distinct, perpendicular to the axis of the prism. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 7.228. Opaque. Lustre metallic. Colour greyish-silver-white. Streak greyish-black.

Massive varieties, amorphous. Structure columnar, radiating, granular, fibrous? compact.

Found near Hüttenburg in Carinthia, at Reichenstein in Silesia, and at Schladming in Stiria.

Titaniate of Iron.

A very indiscriminate class of iron ores, some crystallizing in Cubes and others in Rhomboids, and requiring a careful revision.

The following descriptions have been given of some of the varieties.

a. IRON SAND, No. 389.

Haid. 2.402. Leon. 365. 554.

There are so many loose, granular, and sandy varieties of iron ore found in alluvial soil, that no general description can be given which will comprehend them all. They generally contain titanium, but occasionally consist of magnetic or oligistic iron only.

b. ISERINE. In larger grains, containing about 28 per cent. of oxide of Titanium.

c. MENACCANITE. Containing about 45 per cent.

d. NIGRINE, No. 390.

Phil. 258. Haid. 2.376. Leon. 362.

Haidinger describes this as Rutile; but specimens received in this Country as Nigrine, are altogether different, and resemble Menaccanite in lustre, colour, and appearance of the fractured surfaces.

This may, therefore, be regarded as an uncertain species.

e. AXOTOMOUS IRON, No. 391.

Haid. 2.397. Leon. 366.

Primary form a Rhomboid. CRYST. fig. 106. P,P' = 85° 40' nearly. Cleavage perpendicular to the axis, distinct. Fracture conchoidal. Hard. 5.0, 5.5. Sp.gr. 4.66. Opaque. Lustre imperfect, metallic. Colour black. Streak black.

Found at Gastein in Salzburg, in Sweden, and in Siberia.

f. CRICHTONITE, No. 392.

Haüy, 4.98. Phil. 261. Haid. 2.399. Leon. 367.

Occurs in attached crystals.

Primary form a Rhomboid. CRYST. fig. 106. P,P' = 61° 20', or 85° 40', nearly, according to the planes assumed to be the primary, there being no apparent cleavage planes parallel to either set. Cleavage perpendicular to the axis. Fracture conchoidal. Hard. 4.5. Sp.gr. 4.0. Opaque. Lustre imperfect metallic. Colour black. Streak black.

Found at Oisans in France.

The cleavage and other characters render it probable that this may not differ chemically from the axotomous iron of Mohs.

g. MOHSITE, No. 393.

P.M. and An. 1.221.

Occurs in attached macled crystals.

Primary form a Rhomboid. CRYST. fig. 106 P,P' = 73° 13'. No apparent cleavage. Fracture conchoidal. Hard. 5.5. Opaque. Lustre metallic. Colour black. Streak black. Not magnetic.

Found in Dauphiny, France.

ISOPYRE, No. 310.

P.M. and An. 3.70.

Occurs in amorphous masses in granite. Fracture conchoidal. Hard. 5.5, 6.0. Sp.gr. 2.912. Nearly opaque. Lustre vitreous. Colour black, or greyish-black, sometimes dotted with red. Streak greenish-grey. Slightly magnetic.

Found in the Western part of Cornwall, where it had been called black opal.

ITTNERITE, No. 211.

Leon. 749.

Occurs crystallized in Rhombic dodecahedrons and massive. Structure compact. Fracture uneven. Hard. 5.5. Sp.gr. 2.3. Lustre resinous to vitreous. Colour grey of different shades.

Found at Kaiserstuhl in Swabia.

KAKOXENE, No. 503.

E.J.S. 5.163. Leon. 749.

Occurs in thin fibrous radiating tufts or plates filling narrow fissures in a clayey-brown ironstone at Zbirow in Bohemia. Colour yellow of several shades and sometimes brownish-red.

KARPHOLITE, No. 312.

Phil. 22. Haid. 3.116. Leon. 209.

Occurs in slender crystals and silky fibres.

Primary form unknown. Sp.gr. 2.955. Lustre of the crystals vitreous, of the fibrous masses silky. Colour yellow, sometimes pale.

Found at Schlackenwalde in Bohemia.

KEFFEKILLITE, No. 358.

Leon. 181.

A Mineral from the Crimea, so named by Fisher of Moscow, not analyzed or described.

KILLINITE, No. 223.

Phil. 322. Haid. 3.117. Leon. 750.

Occurs in imbedded imperfect crystals and massive.

Cleavage parallel to the lateral planes and short diagonal of a rhombic prism of about 135°. Phil. Fracture uneven. Hard. 4.0. Sp.gr. 2.698. Translucent, opaque. Lustre dull vitreous. Colour brownish or yellowish-green, or greenish-grey. Streak yellowish-white.

Massive variety, amorphous, structure columnar, promiscuously arranged.

Found at Killiney near Dublin, Ireland.

KNEBELITE, No. 288.

Phil. 206. Haid. 3.118. Leon. 751.

Occurs massive, with a cellular and uneven surface. Fracture imperfectly conchoidal. Hard. Brittle. Difficultly frangible. Sp.gr. 3.714. Opaque. Lustre glistening. Colour grey, with spots of dirty white, brownish-red, brown, and green.

No locality given.

LABRADORITE. *Labrador Felspar. Felspath Opaline*, No. 234.

Haüy, 3.94. Phil. 115. Haid. 2.257. Leon. 430.

Occurs in rolled or imbedded crystalline masses. Cleavage parallel to all the planes of a Doubly oblique prism. CRYST. fig. 95. P,M = 93° 55'. P,T = 114° 26'. M,T = 120° 40' Fracture uneven. Hard. 5.5, 6.5. Sp.gr. 2.69, 2.76. Translucent. Lustre vitreous. Colour grey, white, with rich iridescent colours in particular directions.

Found principally in rolled masses on the coast of Labrador, and in Devonshire imbedded in a trap rock. The white variety, which may possibly be Cleavelandite, is from Greenland.

The above measurements, which were taken on distinct but not bright cleavage planes, approach so very nearly to those of Cleavelandite as to create a doubt whether they really differ.

LATROBITE. *Diploite. Amphodelite?* No. 316.

Phil. 380. Haid. 3.118. Leon. 465.

Occurs in attached and imbedded crystals and massive.

Primary form a Doubly oblique prism. CRYST. fig. 95. Measuring 91°, 93° 30', and 98° 30', nearly. Cleavage parallel to all the primary planes. Fracture uneven. Hard. 5.0, 6.0. Sp.gr. 2.72, 2.8. Translucent. Lustre vitreous. Colour pale red.

Found at Amitok Island, Labrador, and in Finland.

LAUMONITE, No. 217.

Haüy, 3.151. Phil. 45. Haid. 2.234. Leon. 200.

Occurs in attached and aggregated crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 113° 30'. M,M' = 86° 15'. Cleavage parallel to M,M', distinct. Fracture uneven. Sp.gr. 2.2. Translucent, opaque. Lustre vitreous. Colour greyish, yellowish, reddish-white. Streak white.

Massive varieties, amorphous, structure granular.

By exposure to the air it loses its water of crystallization, and becomes friable.

Found at Huelguet in Brittany, in Hungary, Faroe, Iceland, Scotland, and Ireland.

LAVA, No. 250.

Leon. 181. 413.

Occurs as a volcanic product in more or less compact or vesicular masses. Fracture uneven. Hardness and Sp.gr. variable. Translucent, opaque. Lustre vitreous. Colour greyish and greenish-black, brown, red, grey.

Found at Vesuvius, Etna, and other volcanos.

LAZULITE. *Lapis Lazuli*, No. 564.

Haüy, 3.54. Phil. 44. Haid. 2.288. Leon. 136.460.

Occurs in imbedded dodecahedral crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the rhombic dodecahedron, indistinct. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 2.76, 2.94. Translucent, opaque. Lustre vitreous. Colour blue of different shades. Streak paler blue.

Massive varieties. Amorphous, sometimes in small imbedded grains; structure fine granular, compact.

Brought from Persia and China, but neither its locality nor its geological relations are known.

Used in the manufacture of ultramarine, and in jewellery, as ornamental stones

LEAD.

Aluminate of Lead.

a. PLOMBGOMME, No. 151.

Haüy, 3.410. Phil. 338. Haid. 3.140. Leon. 229.

Occurs in small globular and reniform masses, composed of thin concentric layers. Structure of the layers indistinctly fibrous. Fracture uneven. Hard. 4.5, 5.0. Translucent. Colour yellow, sometimes brownish.

Found at Huelguet in Brittany.

Arseniate of Lead.

a. GORLANDITE. *Bleiniere* when in reniform masses, No. 475.

Haüy, 3.385. Phil. 345. Haid. 2.133. Leon. 272.

Occurs in attached crystals, in the form of regular hexagonal prisms, frequently with convex lateral planes, and massive.

Primary form a Rhomboid. CRYST. fig. 106 Cleavage parallel to the lateral planes of the hexagonal prism. Hard. 4.0, 5.0. Sp.gr. 5.0, 6.4. Transparent, translucent. Lustre resinous. Colour pale dull yellow, yellowish and reddish-brown.

Massive varieties, reniform, structure compact. Fracture conchoidal. Sp.gr. 3.9. Opaque. Lustre resinous. Colour brownish-red. From Nertschinsk in Siberia.

Found in Cornwall, at St. Prix in France, and in a few other places.

b. ARSENITE OF LEAD? No. 476.

Specimens of a pale yellow substance in fine fibres, soft, and easily reducible to an impalpable powder, have passed under this name, but we do not find any published account of it.

Carbonate of Lead.

a. CARBONATE OF LEAD, No. 458.

Haüy, 3.365. Phil. 338. Haid. 2.130. Leon. 290.

Occurs in attached crystals, in aggregations of columnar crystals, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M' = 117° 14'. Cleavage parallel to all the primary planes. Fracture conchoidal. Hard. 3.0, 3.5. Sp.gr. 6.465. Transparent, translucent. Lustre adamantine on the cleavage planes, resinous on the fracture surfaces. Colour generally white, occasionally grey, yellow, green, black. Streak white.

Massive varieties, amorphous; structure columnar, granular, compact.

Found in most lead mines, and occasionally in those of other metals, in many parts of Europe, Asia, and America, and used as an ore of lead.

Chloride of Lead.

a. CHLORIDE OF LEAD, No. 63.

Occurs in small, thin, flat, white, opaque crystals, accompanying murio-carbonate of lead from Cornwall.

b. CHLORO-CARBONATE OF LEAD. *Murio-carbonate of Lead*, No. 65.

Haüy, 3.374. Phil. 343. Haid. 2.150. Leon. 294.

Occurs in attached crystals.

Primary form a Square prism. CRYST. fig. 65. Cleavage parallel to the primary planes, distinct. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 6.0. Transparent. Lustre adamantine. Colour white, pale grey, yellow, and green. Streak white.

Found at Matlock, Derbyshire, and in Cornwall.

c. BERZELITE. *Chloro-oxide of Lead*, No. 64.

Haid. 2.151. Leon. 416.

Occurs in crystalline amorphous masses. Cleavage parallel to the lateral planes, and short diagonal of a rhombic prism of 102° 30'. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 7.077. Translucent. Lustre adamantine. Colour yellowish-white, pale yellow, and red.

Found near Churchill, in the Mendip Hills, Somersetshire.

Chromate of Lead.

a. CHROMATE OF LEAD, No. 421.

Haüy, 3.357. Phil. 349. Haid. 2.137. Leon. 337.

Occurs in attached crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 99° 10'. M,M' = 93° 30'. Cleavage parallel to the primary planes, indistinct. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 6.001. Transparent, translucent. Lustre adamantine. Colour red. Streak orange-yellow.

Massive varieties, amorphous; structure columnar, granular.

Found principally at Berezof in Siberia, and recently in Brazil.

Chromate of Lead and Copper

a. VAUQUELINITE, No. 422.

Phil. 350. Haid. 3.167. Leon. 339.

Occurs in minute attached crystals, and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. Fracture uneven. Hard. 2.5, 3.0. Sp gr. 5.5, 5 78. Nearly opaque. Lustre adamantine. Colour greenish-black, black. Streak greenish.

Massive varieties, botryoidal, reniform, amorphous; structure fine granular, compact.

Found at Berezof in Siberia, with chromate of lead.

Molybdate of Lead.

a. CARINTHITE, No. 417.

Haüy, 3.397. Phil. 348. Haid. 2.140. Leon. 340.

Occurs in attached crystals and massive.

Primary form a Square prism. CRYST. fig. 65. Cleavage parallel to the primary planes, and to those of *Mod. c.* CRYST. fig. 68. Fracture uneven. Hard. 3.0. Sp.gr. 6.760. Transparent, translucent. Lustre resinous. Colour yellow of different shades, greenish-red, and red.

Found chiefly in Carinthia, also in Austria, Hungary, and in North America. The red at Moldawa in the Bannat.

Oxide of Lead with Molyb. Carb. Mur. Phosp. and Chromic Acids.

a. PAMPLONITE, No. 418.

E.N.P.J. 12.142.

Occurs in small amorphous concretions in a decom-

posed syenite. Heavy. Sp.gr. 6.0. Colour greenish-yellow.

Found in the Paramo Rico, near Pamplona, South America.

Native Lead.

a. NATIVE LEAD, No. 10.

Phil. 332. Haid. 3.129. Leon. 695.

Occurs in small, amorphous, imbedded masses in lava or some other fused substances. Fracture hackly. Hard. 1.5. Sp.gr. 11.35. Opaque. Lustre metallic. Colour lead-grey. Streak shining.

Found in Madeira and some other places, and at Alston in Cumberland.

Red Oxide of Lead.

a. NATIVE MINIUM, No. 135.

Haüy, 3.352. Phil. 337. Leon. 559.

Occurs in compact and pulverulent amorphous masses, supposed to arise from the decomposition of galena. Hard. 2.0, 2.5. Sp.gr. 4.6. Dull. Colour bright red.

Found in Yorkshire, in Swabia, Siberia, and some other places.

Yellow Oxide of Lead.

a. NATIVE MASSICOT, No. 134.

An. 5.47. Leon.

Occurs in amorphous masses. Fracture earthy. Brittle. Sp.gr. 8.0. Opaque. Dull externally, internally semi-metallic. Colour yellow.

Found at Eschweiler.

Phosphate of Lead.

a. PYROMORPHITE, No. 493.

Haüy, 3.385. Phil. 344. Haid. 2.133. Leon. 272.

Occurs in attached crystals, generally in the form of regular hexagonal prisms, frequently with the lateral planes convex, sometimes slender and fasciculated; and massive.

Primary form a Rhomboid. CRYST. fig. 106. Cleavage parallel to all the planes of the prism, and to the truncation of its terminal edges. Fracture uneven. Sp.gr. 7.098. Transparent, translucent. Lustre resinous. Colour grey, green, brown.

Massive varieties, globular, reniform, botryoidal; structure fibrous. Amorphous structure fibrous, granular, compact.

Found in most lead mines.

b. PHOSPHATO-ARSENIATE OF LEAD, No. 494.

Haüy, 3.385. Phil. 345. Haid. 2.133. Leon. 272.

Occurs in attached and aggregated crystals similar in form and most other characters to phosphate. Colour various shades of yellow.

Scheelate of Lead.

a. SCHEELATE OF LEAD, No. 415.

Phil. 350. Haid. 3.165. Leon. 345.

Occurs in attached and aggregated crystals.

Primary form a Square prism, (CRYST. fig. 65,) of the same dimensions as that of Molybdate of lead. Cleavage perpendicular to the axis of the prism, and parallel to planes of *Mod. c*, CRYST. fig. 68. Fracture conchoidal. Hard. 3.0. Sp.gr. 8.0. Translucent. Lustre resinous. Colour yellowish and brownish-grey.

Found at Zinnewald in Bohemia, and Bleiberg in Carinthia.

Seleniuret of Lead.

a. SELENIURET OF LEAD, No. 47.

An. N.S. 10.233. 284. Leon. 590.

Occurs in amorphous masses; structure granular, and nearly resembling fine-grained galena. Softer than galena. Sp.gr. 7.697. Opaque. Lustre metallic, rather dull. Colour more blue than galena.

Found at Clausthal and Tilkerode in the Hartz, accompanied by some of the following varieties·

b. Seleniuret of lead and cobalt, No. 48.

c. ... ... *copper*, No. 49.

d. Cupriferous seleniuret of lead, No. 50.

e. Seleniuret of lead and mercury, No. 51.

f. ... ... *copper and silver*, No. 52.

These are said to resemble seleniuret of lead so nearly as to be scarcely distinguishable from it.

Sulphate of Lead.

a. ANGLESITE, No. 548.

Haüy, 3.402. Phil. 346. Haid. 2.142. Leon. 249.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. $M,M' = 103° 42'$. Cleavage parallel to the primary planes. Fracture conchoidal. Hard. 2.5, 3.0. Sp.gr. 6.298. Transparent, translucent. Lustre approaching to adamantine. Colour white, sometimes greyish, yellowish, greenish, grey, and brown of several shades, black. Streak white.

Massive varieties, amorphous, structure laminar, granular, compact.

Found in lead and copper mines at Lead hills, Scotland, in Anglesey, in Cornwall, the Hartz, and other places in Europe, and in North America.

Cupreous Sulphate of Lead.

a. LINARITE, No. 549.

Phil. 347. Haid. 2.143. Leon. 251. P.M. and An. 10.267.

Occurs in attached crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 83. $P,M = 96° 25'$. $M,M' = 61°$. Cleavage parallel to P, and to the horizontal diagonals of the terminal planes. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 5.3, 5.43. Transparent, translucent. Lustre adamantine. Colour deep blue. Streak pale blue.

Found at Linares in Spain, and at Lead hills, Scotland.

Sulphate and Carbonate of Lead.

a. LANARKITE. *Sulphato carbonate of Lead*, No. 550.

Phil. 341. Haid. 2.148. Leon. 253.

Occurs in long, slender crystals, single or aggregated into fibrous masses.

Primary form an Oblique rhombic prism, the angles of which have not been ascertained. The crystals are lengthened in the direction of the horizontal diagonals of the terminal planes. Hard. 2.0, 2.5. Sp.gr. 6.8, 7.0. Transparent, translucent. Lustre nearly resinous, but pearly on the cleavage planes. Colour greenish, yellowish, or greyish. Streak white.

Found at Lead hills in Scotland.

b. CALEDONITE. *Cupreous-sulphato-carbonate of Lead*, No. 551.

Phil. 342. Haid. 2.149. Leon. 254.

Occurs in attached crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. $M,M' = 95°$. Cleavage parallel to the primary planes, and to the short diagonal of the prism. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 6.4. Transparent, translucent. Lustre resinous. Colour blue and greenish-blue. Streak bluish or greenish-white.

Found at Lead hills in Scotland.

c. SUZANNITE. *Sulphato-tri-carbonate of Lead*, No. 552.
Phil. 341. Haid. 2.144. Leon. 252.
This Mineral occurs, as carbonate of lime does, under two forms. One an Acute rhomboid, CRYST. fig. 106, P,P′ = 72° 30′; and the other a Right rhombic prism, CRYST. fig. 71, M,M′ = 120°.
Mr. Haidinger has regarded this last as an *Oblique* rhombic prism, a difference of opinion which may perhaps be explained by his own observations on Mr. Levy's *Humboldtite*; the compound figures given by him in *Edinb. Phil. Trans.* 10.217. being purely imaginary.
The cleavage of both forms is perpendicular to the axis, and very distinct. Hard. 2.5. Sp.gr. 6.3. Transparent, translucent. Colour grey-brown, yellow, green of various shades. Streak white.
Found at Lead hills in Scotland.

Sulphuret of Lead.

a. GALENA, No. 83.
Haüy, 3.341. Phil. 332. Haid. 3.13. Leon. 625.
Occurs in attached crystals, and massive.
Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the primary planes. Fracture conchoidal. Hard. 2.5. Sp.gr. 7.568. Opaque. Lustre metallic. Colour lead-grey. Streak the same.
Massive varieties, amorphous, structure granular, compact.
Found abundantly in many places in Europe, Asia, and America.
Sulphuret of lead is occasionally found to contain antimony, arsenic, silver, bismuth, and copper.

Sulphuret of Lead, Antimony, and Copper.

a. BOURNONITE. *Endellione. Triple Sulphuret*, No. 97.
Phil. 336. Haid. 3.5. Leon. 613.
Occurs in attached crystals and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 93° 30′ nearly. Cleavage parallel to the primary planes, and to both the diagonals of the prism. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 5.763. Opaque. Lustre metallic. Colour approaching to steel-grey, sometimes blackish-grey. Streak the same.
Massive varieties, amorphous, structure granular, compact.
Found in Cornwall, and in several parts of Europe, and in Peru.

Vanadiate of Lead.

a. JOHNSTONITE, No. 484.
E.J.S. N.S. 5.166.
Occurs in attached hexagonal crystals, and small globular concretions, frequently sprinkled over a surface of Calamine.
Primary form a Rhomboid. CRYST. fig. 106. Fracture conchoidal. Sp.gr. 6.99, 7.23. Translucent. Opaque. Lustre of the fractured surface resinous. Colour yellow and reddish-brown. Streak white.
Found at Wanlockhead in Scotland.

LEELITE, No. 317.
Phil. 21. Haid. 3.119. Leon. 757.
Occurs in amorphous masses.
Structure compact. Fracture conchoidal. Sp.gr. 2.7. Slightly translucent. Lustre waxy. Colour flesh-red.
Found at Gryphytta in Sweden, and, when first discovered, passed under the name of red hornstone.

LEUCITE. *Amphigene*, No. 233.
Haüy, 3.61. Phil. 107 Haid. 2.220. Leon. 435.
Occurs in imbedded trapezohedral crystals, and massive.
Primary form a Cube. Cleavage parallel to the planes of the cube and rhombic dodecahedron. Fracture conchoidal. Hard. 5.5, 6.0. Sp.gr. 2.483. Transparent to opaque. Lustre vitreous. Colour greyish, yellowish, or reddish-white, and different shades of grey. Streak white.
Massive variety, amorphous, structure granular.
Found in the lavas of Vesuvius, and the basalts of Italy and Bohemia.

LEVYNE, No. 206.
Haid. 3.120. Leon. 758.
Occurs in attached crystals, lining cavities in trap rocks.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 79° 29′. Cleavage parallel to the primary planes. Fracture conchoidal. Hard. 4.0. Sp.gr. 2.15. Translucent. Lustre vitreous. Colour white. Streak white.
Found at Dalsnypen in Faroe, in Ireland, and in a few other places.
It is said by Berzelius to be a variety of *Chabasie*.

LHERZOLITE, No. 359.
Gal. 168. Leon. 505.
Occurs in imperfectly formed crystalline grains, imbedded in greenish-yellow steatite. Sp.gr. 3.54. Transparent. Colour emerald-green.
Found on the banks of Lake Lherz, in the mountains Du Couserans, Pyrenees.

LIGURITE, No. 318.
Phil. 207. Haid. 3.121. Leon. 758.
Occurs in imbedded crystals in a talcose rock.
Primary form an Oblique rhombic prism. CRYST. fig. 63. M,M′ = 140°. Fracture uneven. Hard. 5.0, 6.0. Sp.gr. 3.49. Transparent, translucent. Lustre vitreo-resinous. Colour yellowish-green. Streak greyish-white.
Found on the banks of the Stura in the Apennines.
Specimens of yellowish-green Sphene have been brought to this Country as Ligurite. This, however, cannot be the Mineral examined by Viviani, if his analysis be correct; for his Mineral does not contain a particle of titanic acid, of which Sphene contains from 33 to 40 per cent.

LIMBILITE, No. 360.
Phil. 208. Leon. 533.
Occurs in irregular grains in the volcanic hill of Limbourg. Structure compact. Hard. 6.0, 7.0. Colour honey-yellow.

LIME.

Arseniate of Lime.

a. PHARMACOLITE, No. 466.
Haüy, 1.587. Phil. 178. Haid. 3.135. Leon. 160. E.J.S. 3.302, 6.317.
Occurs generally in small, silky tufts, or minute globular and botryoidal fibrous masses, coating other substances, and very rarely in attached crystals.
Crystallized.
Primary form an Oblique rhombic prism. CRYST. fig. 83. M,M′ = 117° 24′. Cleavage parallel to the oblique diagonals of the terminal planes. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 2.730.

Mineralogy

Transparent, translucent. Lustre vitreous. Colour yellowish-white. Streak white. Thin laminæ are flexible.

Locality unknown.

Fibrous.

Very soft. Sp.gr. 2.64. Translucent, opaque. Lustre vitreous, pearly, dull. Colour white, greyish and reddish-white.

Found at Andreasberg, Hartz, in Thuringia, and some few other places.

b. HAIDINGERITE, No. 467.

E.J.S. 3.303, 6.317. Leon. 160.

Occurs in attached crystals, and in pearly, botryoidal, crystalline coats.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 100°. Cleavage parallel to the short diagonal of the terminal planes, very distinct. Hard. 2.0, 2.5. Sp.gr. 2.848. Transparent, translucent. Lustre vitreous. Colour white. Streak white. Thin laminæ slightly flexible.

Locality unknown.

Boro-silicate of Lime.

a. DATHOLITE, No. 126.

Haüy, 1.590. Phil. 177. Haid. 2.222. Leon. 285.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig 73. M,M′ = 103° 40′: Phil. Cleavage parallel to the lateral planes, very indistinct. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 2.989. Translucent, opaque. Lustre vitreous, that of the fracture surfaces slightly resinous. Colour greyish, yellowish, greenish-white. Streak white.

Massive variety, amorphous, structure granular.

Found at Arendal in Norway.

b. HUMBOLDTITE, No. 427.

Phil. 380. Haid. 2.222. Leon. 286. 789.

Occurs in attached crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,*h*, fig. 91 = 91° 41′. M,M′ = 115° 45′. Levy. Cleavage parallel to the oblique diagonal of the prism. Fracture conchoidal. Hard. 4.5, 5.0. Sp.gr. 2.99. Transparent, translucent, opaque. Lustre vitreous. Colour white, sometimes yellowish. Streak white.

Found in the Tyrol, in the Hartz, in North America, and in the neighbourhood of Edinburgh.

It is probable that this will be found to correspond with *Datholite* in form and measurement, as it does in chemical composition; and that Mr. Levy has been deceived by the imperfection of the crystals he examined.

c. BOTRYOLITE, No. 428.

Hauy, 1.591. Phil. 177. Haid. 2.222. Leon. 287.

Occurs in reniform, globular, and botryoidal masses. Structure fibrous, in concentric coats. Sp.gr. 2.8. Translucent on the edges, sometimes opaque and earthy. Colour pale yellowish and reddish-grey, occasionally black on the surface. Streak white.

Found at Arendal in Norway.

Rhomboidal Carbonate of Lime, **No. 441.**

1. *Crystallized.*

a. CALCITE. *Calcareous Spar. Iceland Crystal.*

Haüy, 1.298. Phil. 147. Haid. 2.83. Leon. 309.

Occurs in attached and imbedded crystals and crystalline masses, and occasionally stalactitic.

Primary form a Rhomboid. CRYST. fig. 106. P, P′ = 105° 5′. Cleavage parallel to the primary planes, very distinct. Fracture conchoidal, seldom observable. Hard. 3.0. Sp.gr. 2.721. Transparent, translucent. Lustre vitreous. Colour generally white, occasionally grey, blue, green, yellow, red, brown, black. Streak white, or slightly coloured.

Found in veins and in rocks of every formation in all parts of the World.

2. *Foliated.*

a. SCHIEFERSPAR. *Slate Spar.*

Haüy, 1.430. Phil. 149. Haid. 2.83. Leon. 316.

Occurs massive. Structure laminar, the laminæ being thin and generally curved or wavy. Sp.gr. about 2.5. Translucent. Lustre vitreous on the edges, pearly on the surface of the laminæ. Colour white, sometimes reddish, yellowish, greenish. Streak white.

Found in England, Scotland, Ireland, and in other parts of the World.

3. *Pearly.*

a. APHRITE. *Ecume de Terre. Schaumerde.*

Phil. 150. Haid. 3.72. Leon. 776.

Occurs in thin, white, pearly scales or plates. Hard. 0.5, 1.0. Sp.gr. 2.5. Opaque. Lustre pearly in a high degree. Colour white. Streak white.

Found in Saxony, Hessia, and some other places.

4. *Columnar.*

a. ANTHRACONITE. *Madreporite.*

Hany, 1.358. Phil. 160. Haid. 2.83. Leon. 317.

Occurs in roundish masses. Structure columnar, diverging. Hard. 3.0. Sp.gr. 2.7. Opaque. Lustre vitreous. Colour greyish-black.

Found in Norway, Sweden, Greenland, and one or two other places.

5. *Fibrous.*

a. STALACTITE.

Haüy, 1.364. Phil. 151. Haid. 2.83. Leon. 319.

Occurs reniform, stalactitic, tubular, and in other imitative shapes. Structure fibrous. Translucent, opaque. Lustre resinous, waxy, sometimes silky. Colour white with shades of grey, brown, red, yellow, and other colours. Streak whitish.

Found in fissures and caverns, in calcareous rocks, and occasionally in metallic veins.

6. *Granular and compact.*

a. MARBLE. *b.* LIMESTONE.

Haüy, 1.359. Phil. 152. Haid. 2.83. Leon. 316.

Occurs massive, the masses sometimes forming considerable mountains.

Those varieties which are capable of receiving a fine polish are commonly termed *Marble,* the purest and most crystalline of which are employed in statuary. The Pentelic, found near Athens, and the Carrara from the Gulf of Genoa, are the most esteemed.

The less pure varieties, which are generally less crystalline in their appearance, and more compact in their structure, although they differ much from each other in colour and composition, pass under the common name of *Limestone,* and are applied to many well-known economical purposes. Some of the common limestones contain a considerable proportion of silex, alumina, and other earths. The *Calp* in Ireland, the *Aberthaw* and the *Lias* in this Country, and the *Septaria,* or Nodules, as they are termed, found in the London clay, and of which the Roman cement is made, are impure

limestones. The impurity, however, rendering them more valuable as cements.

The fracture of the granular varieties is uneven and splintery, that of the more compact is even and flat conchoidal. Hardness and Sp.gr. rather below that of calcareous spar. Translucent to opaque. Lustre variable. Of almost all colours. Streak white or slightly coloured

Found abundantly in every part of the World.

7. *Earthy.*

a. CHALK. *Agaric Mineral. Rock Milk.*

Haüy, 1.362. Phil. 158. 150. Haid. 2.83. Leon. 321.

Chalk occurs in beds of very considerable extent. Fracture earthy. Soft. Sp.gr. about 2.3. Opaque. Dull. Colour white, sometimes yellowish or greyish. Is meagre to the touch.

Agaric Mineral is a spongy carbonate of lime, the particles of which are less coherent than those of chalk, with which it agrees in colour and most of its other characters.

Rock Milk is an absurd name for a variety of carbonate of lime, which occurs in the form of a fine white powder in the crevices of calcareous rocks.

Found in several parts of England, and in other Countries.

8. *Globular Concretions*

a. PISOLITE. *Peastone.*

Haüy, 1.369. Phil. 158. Haid. 2.83. Leon. 319.

Occurs massive, consisting of globules from one-eighth to half an inch in diameter, imbedded in a calcareous cement. Opaque. Colour brownish, reddish, yellowish-white. Streak white.

Found at Carlsbad, and a few other places

b. OOLITE. *Roestone.*

Haüy, 1.360. Phil. 157. Haid. 2.83. Leon. 318.

Occurs massive, in beds of considerable extent, formed of small globules of different sizes, seldom as large as one-eighth of an inch in diameter, cemented together by calcareous matter. Opaque. Dull. Colour greyish, brownish, yellowish white. Streak white.

The Bath stone affords a good example of this substance

9. *Incrusting. Sedimentary.*

a TUFA. *Travertino.*

Haüy, 1.370. Phil. 160. Haid. 2.63. Leon. 320.

The most impure and irregular of all the varieties of carbonate of lime, varying considerably in the cohesion of its particles, from a nearly pulverulent state (some Tufas) to that of a compact building stone. (Travertino.) It is a concrete production of many springs and streams in this and other Countries, and may be observed in abundance at Matlock in Derbyshire, near Cambridge, near Ventnor in the Isle of Wight, and in some other places.

It is found incrusting grass and moss at the edges of the water, and stems, leaves, and other substances immersed in it. Small baskets and birds' nests coated with this deposit, are sold as objects of curiosity.

Prismatic Carbonate of Lime, No. 442.

a. ARRAGONITE. The coralloidal variety, *Flos-ferri.*

Hauy, 1.432. Phil. 161. Haid. 2.79. Leon. 324.

Occurs in attached and imbedded, simple and compound crystals, frequently acicular, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 116° 10′. Cleavage parallel to the lateral planes. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 2.9. Transparent, translucent. Lustre vitreous. Colour white, grey, reddish-brown. Streak greyish-white.

Massive varieties. Globular, reniform, coralloidal, and amorphous. Structure fibrous, either parallel or diverging, and sometimes, although rarely, compact.

Found in several places in England, Scotland, and Ireland, and in many other Countries. The best crystals occur at Arragon, in Spain, whence the name, at Leogang in Salzburg, and near Bilin in Bohemia. And very perfect masses of the branched variety (flos-ferri) at Dufton, and in the Quantock hills in Somersetshire.

b. SATIN SPAR?

Phil. 150. Haid. 2.83. Leon. 315.

Occurs in tabular masses of one or two inches thick, in veins in slaty clay or shale. Structure fibrous, the fibres parallel, generally waved, and always transverse to the direction of the vein. Harder than calcareous spar. Sp.gr. 2.7. Translucent. Lustre silky. Colour white, sometimes yellowish or greyish.

Found at Alston Moor in England, in Scotland, and in North America.

Carbonate of Magnesia and Lime.

1. *Crystallized.*

a. *The surfaces flat, or nearly so.*

BITTERSPAR. *Miemite. Tharandite*, No. 447.

Haüy, 1.427. Phil. 162. Haid. 2.91. Leon. 305.

Occurs in attached and imbedded crystals, and amorphous masses.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 106° 15′. Cleavage parallel to the primary planes, distinct. Fracture conchoidal. Hard. 3.5, 4.0. Sp.gr. 2.884. Transparent, translucent. Lustre vitreous, occasionally pearly. Colour white, grey, black, brown, yellow, green, of different shades. Streak greyish-white.

Found in the Tyrol in talc, in Piedmont, at Miemo in Tuscany, and in some other places. But there are few localities in which good crystals are produced.

b. *The planes curved.*

PEARLSPAR. *Brown Spar* (in part.)

Haüy, 1.421. Phil. 165. Haid. 2.94. Leon. 305.

Occurs in attached and generally aggregated crystals with curved surfaces.

Primary form a Rhomboid. CRYST. fig. 106. Probably of the same angles as bitterspar, but from the curvature of the planes they cannot be measured. Translucent. Lustre pearly. Colour white, sometimes greyish, brownish, or yellowish.

Found in many parts of Europe and America.

2. *Granular.*

a. DOLOMITE. *Magnesian Limestone. Conite.*

Leon. 305.

Occurs in mountain masses. Structure sometimes slaty. Fracture irregular. Softer than common limestone. Translucent, opaque. Colour white, sometimes greyish or yellowish.

The Apennines are partly composed of *Dolomite*, and the *magnesian limestone* is found in an extensive bed lying between Nottingham and Sunderland. It also occurs in other parts of the World. Some of the varieties are flexible when split or cut into

thin slabs. *Conite* is found only in Iceland. Is described as having a fracture imperfectly conchoidal, and is said to scratch glass, whence it is probable that it does not belong to this species. Sp.gr. 3.0. Opaque. Dull. Colour flesh-red.

3. *Compact.*

a. GURHOFIAN.

Phil. 106. Haid. 2.94. Leon. 308.

Occurs massive. Amorphous. Structure compact. Fracture flat conchoidal. Opaque. Dull. Colour white, sometimes yellowish. Streak white.

Found near Gurhoff, in Lower Austria.

Carbonate of Magnesia, Lime and Iron, No. 449.

P.M. and An. 2.231.

a. Occurs crystallized in rhomboids. Sp.gr. 2.927. Colour yellowish white.

Found at Tenzen in the Grisons.

E.J.S. 2.179.

b. Occurs in crystalline masses, cleavable into rhomboidal laminæ. Sp gr. 2.64. Opaque. Colour brown.

Found at Montiers in Savoy.

c. Crystalline masses. Sp.gr. 2.9. Colour violet-blue.

Found at Notre-Dame-du-Pré in Savoy, and is supposed to contain free oxide of iron.

No angles given of either of these varieties, the chemical elements of which differ in their proportions.

Carbonate of Lime and Iron.

a. ANKERITE. *Rohwand. Wandstein* of Stiria. No. 444.

Haid. 2.100. Leon. 308.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 106° 12′. Cleavage parallel to the primary planes. Fracture uneven. Lustre vitreous, inclining to pearly. Hard. 3.5, 4.0. Sp.gr. 3.080. Translucent. Colour white, with tints of grey, brown, red, yellow. Streak white.

Found in Salzburg resting on beds of mica slate, and all along the chain of the Alps, resting on carbonate of iron.

The planes are generally curved, and the measured angle is probably not correct.

b. MESITINE SPAR? No. 448.

E.J.S. 8.181.

Analysis not given, but supposed to contain lime, magnesia, oxides of iron and manganese. Primary form a Rhomboid. CRYST. fig. 107. P,P′ = 107° 14′: *Breit.* Cleavage parallel to the primary planes. Hard. 3.0. Sp.gr. 3.34. 3.37. Transparent, translucent. Lustre vitreous. Colour dark greyish and yellowish-white. Streak white.

Found in small crystals in quartz at Traversella in Piedmont.

Carbonate of Lime and Lead.

a. PLUMBOCALCITE, No. 445.

E.J.S. N.S. 6 79.

Occurs in attached crystals and crystalline masses.

Primary form a Rhomboid. CRYST. fig. 106. P,P′= 105° 5′. Cleavage parallel to the primary planes, distinct. Hard. under 3.0. Sp.gr. 2.824. Transparent, translucent. Lustre vitreous, sometimes pearly. Colour white. Streak white.

Found at Wanlockhead, Lanarkshire, Scotland, among the rubbish of some old workings.

Fluate of Lime.

a. FLUOR. *Fluor Spar*, No. 506.

Haüy, 1.505. Phil. 168. Haid. 2.69. Leon. 576.

Occurs in attached and imbedded crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the regular octahedron, distinct, but seldom with perfect surfaces. Fracture conchoidal. Hard. 4.0. Sp.gr. 3.14. Transparent, translucent. Lustre vitreous. Colour white, grey, black, brown, red, yellow, green, blue, purple. Streak white or slightly coloured

Massive varieties, nodular: amorphous. Structure of the nodular variety large fibrous, or columnar, the fibres divergent. Structure of the amorphous, crystalline, granular, earthy, compact, and occasionally straight or curved laminar.

Crystallized Fluor is found abundantly in England, and in some other parts of Europe. In America it occurs less frequently. The nodular variety is found only in Derbyshire; the granular and earthy in England, Norway, and some parts of Germany; and the compact in Cornwall, the Hartz, and a few other places.

b. FLUO-ARSENIATE OF LIME, No. 507.

An. 6.151.

Occurs as a yellowish crust or coating on quartz or felspar, accompanying the oxide of tin, at Finbo, near Fahlun, in Sweden.

Native Lime.

a. NATIVE LIME, No. 117.

Br.M. pl. No. 1.

Occurs amorphous. Structure earthy. Easily rubbed to a powder. Opaque. Dull. Colour white.

Found near Bath.

Nitrate of Lime.

a. NITRATE OF LIME, No. 519.

Phil. 177. Leon. 248.

Occurs in fibrous efflorescences, or as a fine powder, on the surface of old walls, caverns, and some calcareous rocks. The fibres are often aggregated into silky-looking tufts. Very deliquescent. Taste bitter.

Phosphate of Lime.

a. APATITE. *Asparagus Stone. Moroxite. Phosphorite. Terre de Marmarosch*, No. 485.

Haüy, 1.487. Phil. 167. Haid. 2.73. Leon. 282.

Occurs in attached and imbedded crystals and crystalline masses, massive and earthy.

Primary form a Rhomboid. P,P′ = 88° 41′: Haid. Cleavage parallel to the planes of a regular hexagonal prism. Fracture conchoidal. Hard. 5.0. Sp.gr. 3.18, 3.22. Transparent, translucent. Lustre vitreous, sometimes inclining to resinous. Colour white, grey, brown, reddish, yellow, green, blue, violet. Streak white.

Found in Cumberland, Cornwall, in Saxony, Bohemia, and many other parts of Europe and America.

Massive varieties, globular; nodular; reniform; amorphous. Structure fibrous, granular, compact.

Found at Schlackenwald in Bohemia, and in Estremadura in Spain.

Earthy variety, greyish or greenish-white.

Found near Marmarosch in Hungary.

Scheelate of Lime.

a. TUNGSTEN. *Tungstate of Lime*, No. 413.

Haüy, 4.372. Phil. 256. Haid. 2.113. Leon. 346.

Occurs in attached and imbedded crystals and massive.

Primary form a Square prism. CRYST. fig. 61. Cleavage parallel to *Mod. a* and *c*, fig. 62 and 64. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 5.5,

6.076. Translucent. Lustre vitreous. Colour white, sometimes greyish and yellowish, and greyish and reddish-brown. Streak white.

Found in Cornwall and Cumberland in England, in Bohemia, Sweden, and other places in Europe, and in America.

Silicate of Lime.

a. WOLLASTONITE. *Tabular Spar*, No. 161.

Haüy, 2.438. Phil. 23. Haid. 2.286. Leon. 524. P.M. and An. 10.190.

Occurs in attached and imbedded crystals, and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M=104° 48′. M,M′ = 95° 38′. Cleavage parallel to the terminal plane and horizontal diagonal. Fracture uneven. Hard. 4.0, 5.0. Sp.gr. 2.8, 2.86. Transparent, translucent. Lustre vitreous, in some varieties pearly on the cleavage surfaces. Colour white, sometimes greyish, brownish, reddish, yellowish, greenish. Streak white.

Massive varieties, amorphous, composed of small columnar crystals lying in all directions, or fibrous, the fibres parallel or divergent.

Found in very perfect crystals at Vesuvius. Its other localities are Capo di Bove near Rome, the Bannat, Lake George in North America, and a few other places.

b. OKENITE, No. 162.

E J.S. N.S. 3.27.

Occurs in fibrous masses, having a radiated structure. Hard. 4.0, 5.0. Sp.gr. 2.28. Colour white.

Found in amygdaloid, at Disco Island, Greenland.

Sulphate of Lime, No. 532.

a. Crystallized.

SELENITE. *Gypsum.*

b. Massive.

ALABASTER. *Gypsum.*

Haüy, 1.527. Phil. 174. Haid. 2.57. Leon. 122.

Occurs in attached and imbedded crystals, and massive.

Primary form an Oblique rhombic prism. P,M = 111° 34′; M,M′ = 138° 38′; Levy. Cleavage parallel to the oblique diagonals, very distinct, and parallel to the primary planes, indistinct. Fracture indistinct. Hard. 1.5, 2.0. Sp.gr. 2.310, 2.5. Transparent, translucent. Lustre vitreous, on cleavage planes pearly. Colour white, occasionally grey, reddish, yellow, blue. Streak white.

Massive varieties, globular and nodular, structure granular. Amorphous, structure granular, earthy, compact, fibrous, scaly, the scales slightly coherent.

Found in very many parts of Europe and America, and probably in other parts of the World. It is abundant in imbedded crystals at Shotover in Oxfordshire, and has occurred in very perfect crystals at Bex in Swisserland.

When calcined and reduced to powder, it is Plaster of Paris. It enters into the composition of some kinds of porcelain and glass. Is employed in agriculture as a manure, and forms the paste of crayons for drawing. The compact varieties are employed in sculpture.

Anhydrous Sulphate of Lime.

a. ANHYDRITE. *Muriacite. Pierre de Trippes. Vulpinite*, No. 533.

Haüy, 1.562. Phil. 172. Haid. 2.62. Leon. 267.

Occurs in attached crystals, rarely well formed, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 100° 8′. Cleavage parallel to the lateral planes, indistinct; to the terminal planes and their two diagonals very distinct. Fracture uneven. Hard. 3.0, 3.5. Sp.gr. 2.5, 3.0. Transparent, translucent. Lustre vitreous, pearly on the cleavage surfaces. Colour white, grey, pale red, blue, violet. Streak greyish-white.

Massive varieties, nodular, contorted, amorphous. Structure granular, compact, fibrous.

Found at Halle in the Tyrol, at Bex in Swisserland, and in several other parts of Europe.

Titaniate of Lime, &c.

a. PYROCHLORE, No. 395.

E.J.S. 6.358.

Occurs in imbedded octahedral crystals.

Primary form a Cube. CRYST. fig. 56. Fracture uneven. Hard. 5 0. Sp gr. 4.21. Translucent, opaque. Colour reddish-brown. Streak pale.

Found in Norway and Siberia.

MAGNESIA.

Borate of Magnesia.

a. BORACITE, No. 425.

Haüy, 2.56. Phil. 181. Haid. 2.347. Leon. 287.

Occurs in imbedded crystals.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the octahedron, very indistinct. Fracture uneven, imperfectly conchoidal. Hard. 7.0. Sp.gr. 2.97. Transparent, translucent. Lustre vitreous. Colour greyish, yellowish, and greenish-white. Streak white.

Found only at Segeberg in Holstein, and Lüneburg in Brunswick.

Carbonate of Magnesia.

a. MAGNESITE, No. 466.

Phil. 179. Haid. 3.121. Leon. 302.

Occurs in acicular crystals, massive, and in powder. Colour generally white, occasionally greyish and yellowish.

The *massive varieties* are found in nodular and stalactitic forms and amorphous. Fracture, hardness, and specific gravity variable, according as the Mineral is more or less compact or earthy.

Found in several parts of Europe, in India, and abundantly at Hoboken in North America.

Carbonate of Magnesia and Iron.

a. BREUNNERIT, No. 450.

Phil. 378. Haid. 2.99. Leon. 309.

Occurs in imbedded crystals.

Primary form a Rhomboid. CRYST. fig. 106. P,P′= 107° 30′. Cleavage parallel to the primary planes, very distinct. Fracture conchoidal. Hard. 4.0, 4.5. Sp.gr. 3.0, 3.2. Transparent, translucent. Lustre vitreous. Colour yellow, of different shades, and black. Streak white.

Found at Zillerthal and other places in Salzburg, and in the Tyrol.

Hydrate of Magnesia.

a. SHEPARDITE, No. 141.

Phil. 95. Haid. 3.112. Leon. 244.

Occurs rarely in attached or imbedded hexagonal prisms, generally in laminar masses and fibrous.

Primary form a Rhomboid. CRYST. fig. 106. P,P′,

unknown. Hard. 1.0, 1.5. Sp.gr. 2.33, 2.63. Transparent, translucent. Lustre pearly. Colour white, greenish-white. Streak white.

The fibrous variety is the *Nemalite* of Nuttall.

Found at Hoboken in New Jersey, North America, and in the Isle of Unst, Shetland.

Phosphate of Magnesia.

a. WAGNERIT, No. 486.

Haid. 3.169. Leon. 277. P.M. and An. 1.133.

Occurs in attached or imbedded crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 109° 20′. M,M′ = 95° 25′. Cleavage indistinct, parallel to the horizontal diagonal. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 3.01. Transparent, translucent. Lustre vitreous. Colour greyish and reddish-yellow. Streak white.

Found at Hollgraben in Salzburg, and is said to have occurred in the United States.

Silicate of Magnesia.

a. MARMOLITE, No. 167.

Haid. 3.124. Leon. 762.

Occurs massive; structure columnar, irregularly intersecting. The columnar portions are foliated, having a cleavage in two directions intersecting each other. Hard. 3.5. Sp.gr. 2.47. Translucent. Opaque. Lustre pearly. Colour pale yellowish and greyish-green

Found at Hoboken in New Jersey, North America.

It is probable that the serpentines are also silicates of magnesia, and for the present we include them in this class

b. SERPENTINE, No. 163.

Phil. 97. Haid. 3.151. Leon. 777

Occurs in imbedded crystals and massive. Fracture conchoidal, uneven, splintery. Hard. 3.0. Sp.gr. 2.2, 2.6. Nearly opaque. Lustre resinous, dull. Colour dull greenish-yellow, and various shades of green, sometimes very dark and spotted with red. Streak white, shining.

Found in all parts of the World in beds and mountain masses.

The *Steatoid* of Möller, E.J.S. N.S. 3.31, occurs in crystals at Snarum in Norway, and is said to be a variety of serpentine.

c. STEATITE. *Soap Stone. Speckstein. Talc Steatite*, No. 164.

Haüy, 2.493. Phil. 118. Haid. 3.157. Leon. 188, 223.

Occurs in amorphous masses, sometimes containing imbedded crystals of the same substance, of the forms of quartz and carbonate of lime. Structure compact. Fracture uneven, splintery. Soft. Sp.gr. 2.6, 2.63. Opaque. Dull. Colour yellowish and greyish-white. Streak shining. Feels greasy.

Said to be found in many parts of the World, but it is probable that several distinct Minerals, merely on account of their soapy or greasy feel, have been so named.

d. MEERSCHAUM, No. 165

Phil. 180. Leon. 222.

Occurs in imbedded masses. Structure earthy. Fracture uneven. Opaque. Dull. Colour white, sometimes slightly yellowish or greyish. Streak white.

Found in Greece, the Crimea, and some other parts of Europe.

Sulphate of Magnesia.

a. EPSOMITE. *Epsom Salt*, No. 535.

Haüy, 2.51. Phil. 180. Haid. 2.48. Leon. 116.

Occurs botryoidal, reniform, massive, as a crust on the surface of other bodies, and in solution in Mineral waters. Structure fibrous, sometimes earthy. Fracture, when observable, conchoidal. Hard. of artificial crystals 2.0, 2.5. Sp.gr. 1.75. Transparent, translucent. Lustre vitreous. Colour white. Streak white.

Found on the surface of decomposing schist, in coal pits, on old walls, and in other situations.

Sulphate of Magnesia and Soda.

a. BLOEDITE, No. 537.

Haid. 3.79. Leon. 125.

Occurs in fibrous masses, accompanying the Polyhallite at Ischel in Upper Austria. Fracture uneven. Translucent. Lustre nearly vitreous. Colour red.

MANGANESE.

ARSENIURET OF MANGANESE? No. 39.

Inst. J. 1829, 2.381.

Occurs on foliated galena. Structure fine granular. Fracture uneven. Brittle. Sp.gr. 5.55. Opaque. Lustre metallic. Colour whitish-grey, but becoming dull and covered with a fine blackish powder after exposure to the air.

Supposed to have been found in Saxony.

Carbonate of Manganese.

a. KÖHLERITE, No. 451.

Phil. 246. Haid. 2.106. Leon. 299.

Occurs in attached crystals and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ about 107°. Cleavage parallel to the primary planes. Fracture uneven Hard. 3.5. Sp.gr. 3.59. Translucent. Lustre vitreous, on cleavage surfaces rather pearly. Colour rose-red, sometimes brownish. Streak white.

Massive varieties, globular, botryoidal. Structure fibrous, compact. Amorphous, structure granular, fibrous, compact.

Found at Kapnic and Nagyak in Transylvania, and in Saxony, the Hartz, and other places.

Oxide of Manganese.

a. MANGANITE, No. 118.

E.J.S. 4.41.

Occurs in attached and imbedded crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 99° 30′. Cleavage parallel to the lateral planes and both diagonals. Fracture uneven. Hard. 4.0, 4.25. Sp.gr. 4.32. Opaque. Lustre imperfect metallic. Colour dark brownish or greyish-black. Streak reddish-brown.

Massive varieties, amorphous. Structure crystalline, granular, large fibrous.

Found at Ilefeld in the Hartz, and in other places.

b. VARVICITE, No. 119.

P.M. and An. 5.209.

Occurs massive, and resembles Manganite in colour, but is much softer, and soils the fingers more. Sp.gr. 4.819.

Found in Warwickshire.

c. PYROLUSITE, No. 120.

E.J.S. 9.304.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ about 93° 40′. Levy. Cleavage parallel to the lateral planes and short diagonal, indistinct. Hard. 2.0, 2.5. Sp.gr. 4.82, 4.94. Opaque. Lustre metallic. Colour iron-black. Streak black.

Massive varieties, reniform, botryoidal, amorphous. Structure fibrous, granular.

Found in Thuringia and many other places in Europe, and in Brazil, *but never at Ilefeld*, with the Manganite.

d. PSILOMELANE, No. 121.

E.J.S. 4.47.

Occurs in reniform, botryoidal, and fruticose shapes, and amorphous. Structure indistinctly fibrous and granular, compact. Fracture conchoidal, even. Hard. 5.0, 6.0. Sp.gr. 4.145. Opaque. Lustre imperfect metallic. Colour bluish and greyish-black. Streak brownish-black.

Found in most depositories of manganese ores.

e. HAUSMANNITE, No. 122.

E.J S. 4.46.

Occurs in attached octahedral crystals, and massive.

Primary form a Square prism. CRYST. fig. 61. *c,c′*, fig. 64, = 105° 25′. Cleavage parallel to P,C, and *a*, fig. 62. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 4.722. Opaque. Lustre imperfect metallic. Colour brownish-black.

Found at Ilmenau in Thuringia.

f. BRAUNITE, No. 123.

E.J.S. 4.48.

Occurs in attached and imbedded crystals and massive. Primary form a Square prism. CRYST. fig. 64. c,c′, fig. 67, = 109° 53′. Cleavage parallel to c, distinct. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 4.818. Opaque. Lustre imperfect metallic. Colour dark brownish-black. Streak the same.

Found at Elgersburg and at Wunsiadel, and perhaps in Thuringia.

Oxide of Manganese, Iron, and Copper.

a. BLACK COPPER. *Black Oxide of Copper*, No. 132.

Leon. 564.

Occurs in amorphous masses. Structure earthy. Soft, friable. Opaque. Dull. Colour black.

Found in most copper mines.

Oxide of Manganese and Copper.

a. CUPREOUS MANGANESE, No. 133.

Haid. 3.92. Leon. 755.

Occurs reniform, botryoidal, and amorphous. Structure compact. Fracture imperfect conchoidal. Sp.gr. 3.197, 3.216. Opaque. Lustre resinous. Colour bluish-black. Streak the same.

Found in Bohemia and ? in Chili.

Phosphate of Manganese and Iron.

a. ULLMANNITE, No. 490.

Phil. 248. Haid. 3.136. Leon. 284.

Occurs massive. Cleavage in three directions perpendicular to each other. Fracture flat conchoidal. Hard. 5.0, 5.5. Sp.gr. 3.44, 3.77. Opaquo. Lustre resinous. Colour reddish or brownish-black. Streak yellowish-grey.

Found near Limoges in France, and ? near Pennsylvania, North America.

b. HETEPOZITE, No. 491.

E.J.S. N.S. 3.359.

Occurs in scaly masses. Cleavage in three directions, giving an Oblique rhombic prism of about 100°. Hard. about 5. Sp.gr. 3.524. Lustre resinous. Colour greenish or bluish-grey.

Found near Limoges.

c. HURAULITE, No. 492.

E.J.S. N.S. 3.359.

Bi-silicate of Manganese.

a. STRÖMITE, No. 169.

Occurs in minute crystals. Hard. about 4.0. Sp.gr. 2.27. Transparent. Lustre vitreous. Colour reddish-yellow.

Found near Limoges.

Phil. 245. Haid. 3.122. Leon. 520.

Occurs massive. Structure crystalline. Cleavage parallel to the lateral planes of a prism of about 92° 30′, and to both its diagonals. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 3.54. Slightly translucent. Colour red.

Found in Sweden, and at Franklin in New Jersey, North America.

Compounds of silica, oxide of manganese, and carbonate of manganese have been indistinctly described under the names of Allagite, Rhodonite, Photizite, and Hornmangan, but whether they are distinct species may perhaps be questioned. Specimens have appeared in this Country under these names, but little resembling in their characters the published descriptions.

Sulphuret of Manganese.

a. KOBELLITE, No. 70.

Haüy, 4.268. Phil. 246. Haid. 3.31. Leon. 656.

Primary form a Cube. CRYST. fig. 51. Cleavage parallel to P, distinct. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 4.014. Opaque. Lustre imperfect metallic. Colour, when first fractured, dark steel-grey, but becomes greyish-black by exposure to the air. Streak dark green.

Massive varieties, amorphous, structure granular, compact.

Found at Nagyag in Transylvania, and ? in Cornwall.

MELLILITE, No. 361.

Haüy, 4.504. Phil. 208. Haid. 3.125. Leon. 213, 760.

Occurs in attached crystals.

Primary form a Square prism. CRYST. fig. 65. Translucent, opaque. Colour reddish and greyish-yellow, and brownish-red.

Found at Tivoli and Capo di Bove near Rome.

MERCURY.

Chloride of Mercury.

BAUMERITE. *Horn Mercury. Muriate of Mercury*, No. 68.

Haüy, 3.331. Phil. 359. Haid. 2.156. Leon. 580

Occurs in attached crystals, and in tubercular crusts.

Primary form a Square prism. CRYST. fig. 65. Cleavage parallel to the lateral planes. Fracture conchoidal. Hard. 1.0, 2.0. Sp.gr. 6.482. Translucent. Lustre adamantine. Colour yellowish or pale grey. Streak white.

Found with other ores of Mercury in Bohemia, the Palatinate, Spain, and principally at Moschel-andsberg, in Deuxponts.

Native Mercury.

a. MERCURY, No. 12.

Haüy, 3.297. Phil. 357. Haid. 2.432. Leon. 696.

Fluid. Occurs in small cavities or crevices of the rock in which it is found, and is frequently accom-

panied by red silver. Sp.gr. 13.6. Opaque. Lustre bright metallic. Colour tin-white.

Its principal localities are Idria in Carniola, and Almaden in Spain.

b. NATIVE AMALGAM, No. 13.

Haüy, 3.297. Phil. 357. Haid. 2.431. Leon. 698.

Occurs in attached and imbedded crystals, and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage flat conchoidal, very indistinct. Hard. 3.0. 3.5. Sp.gr. 13.755. Opaque. Lustre bright metallic. Colour silver white. Streak the same.

Massive variety, amorphous. Structure compact. It is sometimes rendered semi-fluid by mixture with fluid mercury.

Found in Hungary, the Palatinate, Deuxponts, and in France, Spain, and Sweden.

Sulphuret of Mercury.

a. CINNABAR. *Hepatic Cinnabar. Liverore*, No. 92.

Haüy, 3.313. Phil. 358. Haid. 3.44. Leon. 631.

Occurs in attached crystals and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 71° 48′. Cleavage distinct, parallel to plane *e*, fig. 111. Fracture conchoidal. Hard. 2.0, 2,5. Sp.gr. 8.1. Transparent, translucent. Lustre adamantine. Colour bright red, and darker shades to reddish-grey. Streak scarlet.

Massive varieties, amorphous. Structure granular to compact, sometimes fibrous and pulverulent.

The *Hepatic* and *Bituminous Cinnabar* appear to be mixtures of this ore with shale and coarse coal.

Found in Europe, chiefly at Idria in Carniola, at Almaden in Spain, and in the Palatinate, and in several parts of Mexico and South America.

MESOLE, No. 209.

Haid. 3.126. Leon. 206.

Occurs in globular and reniform masses, sometimes imbedded, but generally covering a thin stratum of Mesoline. Structure fibrous, foliated, radiating. Hard. 3.5. Sp gr. 2.37. Translucent. Lustre pearly. Colour white, sometimes yellowish.

Found in the Faroe Islands.

MESOTYPE. *Natrolite*, No. 207.

Haüy, 3.179. Phil. 123. Haid. 2.236. Leon. 204.

Occurs in attached crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 91° 10′. Cleavage parallel to the lateral planes. Fracture conchoidal. Hard. 5.0, 5.5. Sp.gr. 2.249. Transparent, translucent. Lustre vitreous. Colour white, with shades of grey, red, and yellow. Streak white.

Massive varieties, globular and reniform. Structure fibrous, radiating. Surface drusy.

Found in Iceland, the Faroe Islands, Scotland, Ireland, and in many other places, lining cavities in basaltic and porphyritic rocks and ancient lavas.

MESOLITE. *Needle Stone*, No. 208.

Corresponds nearly with the preceding description, but the angle of the prism is 91° 20′.

MICA.

It is certain that several distinct species of Minerals are included under this name, merely because they may be easily split into *very thin, shining* plates, but they cannot at present be distinguished by any characters which have been hitherto given. The following description of crystalline forms applies principally to the micas from Vesuvius.

a. *Rhomboidal*, No. 258.

Haüy, 3.111. Phil. 106. Haid. 2.198. Leon. 437.

Occurs in attached hexagonal prisms, and massive.

Primary form a Rhomboid. CRYST. fig. 106. Cleavage very distinct, perpendicular to the axis. Fracture not observable. Hardness of the cleavage surfaces 2.0. 2.5, that of the edges being 4.5, 5.5. Sp.gr. 2.7, 3.0. Transparent, translucent. Lustre vitreous, pearly on the cleavage surfaces. Colour white, grey, black, brown, pale red, dull yellow, green. Streak white, grey.

Massive varieties, globular, structure fibrous, foliated. Amorphous, structure foliated, granular, fibrous.

Found in primitive rocks in all parts of the World, and abundantly in the masses ejected from Vesuvius.

b. *Oblique prismatic*, No. 259.

The preceding references and descriptions will probably apply to this variety, with the exception of the crystalline form, which is an Oblique rhombic prism. CRYST. fig. 83. P,M = 98° 40′. M,M′ = 120°. Phil.

c. LEPIDOLITE. *Lilac Mica*, No. 260.

Haüy, 3.116. Phil. 141. Haid. 2.202. Leon. 451.

Occurs in amorphous masses, composed generally of small, thin, flexible scales. Fracture uneven. Sp.gr. 2.832. The scales or plates are translucent. Colour pearl-grey, rose and purple-red, and greenish.

Found at Rozena in Moravia, at Utö in Sweden, in North America, and some few other places.

d. MARGARITE. *Pearl Mica*, No. 261.

Phil. 208. Haid. 2.204. Leon. 766.

Occurs in thin, hexagonal, attached crystals, and in masses of small, thin, shining laminæ.

Primary form a Rhomboid. CRYST. fig. 56. Cleavage distinct, perpendicular to the axis. Fracture not observable. Hard. 3.5, 4.5. Sp.gr. 3.032. Translucent. Lustre pearly, bright. Colour greyish, reddish, and yellowish-white. Streak white.

Found at Sterzing in the Tyrol.

e. RUBELLAN. *Red Mica?* No. 262.

Leon. 774.

Occurs in small, imbedded, hexagonal, micaceous plates, not elastic. Soft. Sp.gr. 2.5, 2.7. Colour reddish-brown.

f. ODERIT. *Black Mica?* No. 263.

Occurs in masses which may be split into thin leaves like mica. It is opaque and black, with very little lustre, and is probably mica, containing some foreign matter, which has altered its usual appearance.

Found in Sweden.

MOLYBDENUM.

Sulphuret of Molybdenum.

a. MOLYBDENITE, No. 107.

Haüy, 4.326. Phil. 248. Haid. 3.18. Leon. 667.

Occurs in imbedded hexagonal crystals, and massive.

Primary form a Rhomboid. Cleavage very distinct, perpendicular to the axis. Fracture not observable. Hard. 1.0, 1.5. Sp.gr. 4.5, 4.7. Opaque. Lustre metallic. Colour lead-grey. Streak the same. Thin laminæ very flexible.

Massive variety, amorphous, structure granular, foliated.

Found in Saxony and Bohemia, and in other places in Europe and America.

OXIDE OF MOLYBDENUM, No. 416.
Phil. 249.
Occurs as a crust on the sulphuret, and in thin layers between its laminæ. Structure earthy, and very thin fibrous. Friable. Dull. Colour pale yellow.
Found in Norway, Scotland, and North America. Has not been analyzed.

MONTICELLITE, No. 362.
P.M. and An. 10.265.
A Mineral from Vesuvius, nearly resembling Peridot in its form and measurements, but requiring further examination of better specimens for the purpose of a more exact description.

MURCHISONITE, No. 363.
P.M. and An. 1.448.
Occurs in imbedded crystals and crystalline masses.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,*h*, fig. 91 = 106° 50′. Cleavage distinct parallel to P and to both its diagonals. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 2.509. Translucent, opaque. Lustre vitreous, pearly on the plane *h*. Colour white, with a slight tinge of red.
Found imbedded in the new red sandstone at Dawlish, and at Heavitree, near Exeter, Devonshire.
The inclination of P on *h* agrees very nearly, if not exactly, with the measurement on corresponding planes of the *moon-stone* of Ceylon, the peculiar lustre of which is observable, as in Murchisonite, only on the plane *h*.

MURIATIC ACID GAS, *Chlorine*, No. 58.
Occurs in the state of gas. Transparent. Sp.gr. 1.274. Odour pungent. Taste acid.
Found in the neighbourhood of active volcanoes.

NECRONITE, No. 364.
Appears from its cleavage, hardness, and some other characters to be felspar.

NEPHELINE. *Sommite*, No. 239.
Haüy, 3.347. Phil. 125. Haid. 2.250. Leon. 468.
Occurs in attached hexagonal prisms. Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 88° 55′. Haid. Cleavage *indistinct*, parallel to the planes of the hexagonal prism. Fracture conchoidal. Hard. 6.0. Sp.gr. 2.56. Transparent, translucent. Lustre vitreous. Colour white. Streak white.
Found among the matter ejected from Vesuvius.

Nickel.

ARSENIATE OF NICKEL, No. 474.
Haüy, 3.421. Phil. 284. Haid. 2.448. Leon. 164.
Occurs as a powdery crust on the surface of arseniuret of nickel, and massive. Opaque. Dull. Colour green, and greenish-white.
Found accompanying arseniuret of nickel, and produced from the decomposition of that substance.

Arseniuret of Nickel.

COPPER NICKEL, No. 28.
Haüy, 3.417. Phil. 283. Haid. 2.446. Leon. 678.
Occurs in botryoidal and reniform masses, with a fibrous structure; more commonly amorphous. Structure compact. Fracture uneven. Splintery. Hard. 5.0, 5.5. Sp.gr. 7.65. Opaque. Lustre metallic. Colour yellowish and greyish-red of different shades. Streak pale brownish-black.
Found in Cornwall, Scotland, Saxony, Bohemia, and other parts of Europe, and in South America.

OXIDE OF NICKEL, No. 130.
Phil. 284.
Occurs in a green Mineral named Pimelite, but whether combined with silica, or merely colouring hydrous quartz, appears uncertain.
Found in Serpentine in Silesia.

Sulphuret of Nickel.

NATIVE NICKEL. *Capillary Nickel*, No. 76.
Haüy, 3.412. Phil. 282. Haid. 3.129. Leon. 651.
Occurs in regular hexagonal capillary crystals.
Primary form a Rhomboid. CRYST. fig. 106. Opaque. Lustre metallic. Colour yellow, sometimes greyish.
Found in Wales and Cornwall in England, and in Saxony, Bohemia, and the Hartz.

Sulpho-arseniuret of Nickel.

NICKELGLANZ. *Grey Nickel*, No. 115.
An. 15.147. Leon. 652
Occurs massive. Structure granular. Fracture of the mass uneven, the separate grains foliated. Easily frangible. Sp.gr. 6.129. Opaque. Lustre metallic. Colour pale lead-grey, becoming reddish by tarnish.
Found in Sweden and in the Hartz.

NUTTALLITE, No. 365.
Haid. 3.133. Leon. 765.
Occurs in attached and imbedded crystals.
Primary form a Square prism. CRYST. fig. 65, of the same dimensions as Scapolite. Cleavage parallel to the lateral planes. Fracture uneven. Hard. 4.0, 4.5. Translucent. Lustre vitreous. Colour grey.
Found at Bolton in Massachusetts. And probably some of the dark grey Scapolites from Finland will be found to belong to this species.

OBSIDIAN. *Marckanite*, No. 249.
Haüy, 3.101. Phil. 112. Haid. 2.337. Leon. 413.
Occurs massive and in rolled grains. Structure compact. Fracture conchoidal. Hard. 6.0, 7.0. Sp.gr. 2.35, 2.40. Transparent, opaque. Lustre vitreous. Colour greyish-brown, greenish or brownish-black, black, dull red, and dull green.
Found in the neighbourhood of most volcanoes, and in beds and veins traversing rocks in many parts of Europe, Asia, and America.
Obsidian, Pitchstone, Pearlstone, and Pumice have been considered as belonging to the same Mineral species, from the apparent passage of one into the other, and the consequent absence of exact characters by which they may be distinguished. There appears, however, a chemical difference in their composition; the Pitchstone and Pearlstone containing water, which the others do not; on which account they have been kept separate in this Treatise.

OSMELITE, No. 366.
P.M. and An. 3.71.
Is said to consist of thin prismatic concretions, either scopiformly or stellularly arranged, and these again collected into masses of coarse, granular concretions. Cleavage apparent in only one direction. Hard. 4.0, 5.0. Sp.gr. about 2.8. Translucent. Colour whitish, yellowish, and brownish-grey. Feels greasy. Odour strong clayey. Taste like clay, and seems to dissolve in the mouth, but without producing any apparent change in the substance.
Found at Niederkirchen, near Wolfstein, on the Rhine.

OSMIUM, a metal found combined with Iridium, in small

grains among the platina in South America and Russia. See IRIDIUM.

OSTRANITE, No. 367.
E.N.P.J. 4.186. Leon. 765.
Is said to occur crystallized in the form of a Right rhombic prism, of about 96°. Hard. about 6.5. Sp.gr. 4.32. Lustre vitreous. Colour dark brown.
Found in Norway, and supposed by M. Breithaupt to be a new metallic oxide.

PALLADIUM, No. 14.
Haüy, 3.230. Phil. 325. Haid. 3.134. Leon.
Occurs in rolled grains accompanying the native platina of Brazil, and in minute particles, imbedded in and combined with much of the native gold of Brazil.
Structure of the rolled grains fibrous, divergent. Sp.gr. 11.8. Opaque. Lustre metallic. Colour whitish steel-grey.

PEARLSTONE, No. 245.
Phil. 112. Haid. 2.337. Leon. 182.
Occurs massive. Structure granular, the grains varying in size, and formed of thin concentric laminæ. Fracture uneven. Hard. 4.5, 5.0. Sp.gr. 2.34. Translucent, opaque. Lustre pearly. Colour grey, greyish-black, blackish or reddish-brown.
Found principally at Tokay, in Hungary, also at Cabo da Gato, in Spain, and in a few other places.
See OBSIDIAN.

PEKTOLITE, No. 225.
E.J.S. 9.364.
Occurs in spheroidal masses. Structure fibrous, radiating. Hard. 4.5, 5.5. Sp.gr. 2.69. Nearly opaque. Lustre pearly. Colour greyish-white.
Found on Natrolite at Monte Baldo, South Tyrol.

PERIDOT. *Chrysolite. Olivine? Hyalosiderite?* No. 283.
Haüy, 2.465. Phil. 95. 96. Haid. 2.345. Leon. 530.
Occurs in attached, imbedded, and loose crystals, and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 120°. Levy. Fracture conchoidal. Hard. 6.5, 7.0. Sp.gr. 3.441. Transparent, translucent. Lustre vitreous. Colour green of various shades, sometimes yellowish or brownish. Streak white.
Massive varieties, amorphous. Composition granular, the grains slightly coherent.
The locality of the Chrysolite used in jewellery is not known, but is supposed to be Upper Egypt. Olivine occurs in basalt and lava in Bohemia, Hungary, on the banks of the Rhine, and in other places.

PETALITE, No. 229.
Haüy, 3.137. Phil. 143. Haid. 2.248. Leon. 416.
Occurs in masses composed of smaller crystalline masses, promiscuously aggregated, sometimes so minute as to appear compact. Cleavage parallel to the lateral planes and both diagonals of a rhombic prism of about 100°. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 2.44. Translucent. Lustre vitreous. Colour white. Streak white.
Found at Utön in Sweden, and in North America.

PICROLITE, No. 251.
Phil. 209. Haid. 3.136. Leon. 225.
Occurs massive. Structure thin fibrous. Fracture splintery. Hard. 3.0, 6.0. Nearly opaque. Little lustre, inclining to pearly. Colour yellowish-green.
Found at Taberg and Nordmarken in Sweden.

PICROSMINE, No. 252.
Haid. 3.137. Leon. 512, 768.
Occurs crystallized and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 117° 49′. Cleavage distinct parallel to P, indistinct parallel to the long diagonal and to M. Fracture indistinct, uneven. Hard. 2.5, 3.0. Sp.gr. 2.66. Nearly opaque. Lustre dull vitreous, pearly on the surface M. Colour greenish-white, green of several shades, sometimes blackish. Streak white.
Massive varieties: structure thin fibrous, fracture splintery; granular to compact, fracture earthy.
Found at Engelsburg in Bohemia.

PINITE, No. 266.
Haüy, 2.353. Phil. 80. Haid. 3 139. Leon. 464.
Occurs in imbedded crystals, which are generally hexagonal prisms.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ unknown. Cleavage very indistinct. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 2.78, 2.98. Opaque. Lustre slightly resinous. Colour greenish-grey, blackish-brown, brown, blackish-green.
Found in Saxony, Auvergne, England, and some other parts of Europe, and in North America.

PINGUITE, No. 368.
E.N.P.J. 9.382. Leon. 468.
Occurs massive at Beschert-Gluck, Saxony, and is said to resemble Bole and Green iron earth; two names under which several substances differing in most of their characters appear to have been classed. Hence they afford little indication of the characters of Pinguite.

PITCHSTONE, No. 246.
Phil. 130. Haid. 2.337. Leon. 181.
Occurs massive. Structure compact, sometimes slaty. Fracture imperfect conchoidal, one of the characters by which it is distinguished from Obsidian. Hard. 5.0, 6.0. Sp.gr. 2.3, 2.7. Translucent, opaque. Lustre resino-vitreous. Colour grey, black, brown, red, yellow, green, blue, dull and sometimes variously mixed.
Found at Meissner in Saxony, in Ireland, the Western Islands of Scotland, and in other places.
See OBSIDIAN.

PLATINA, No. 15.
Haüy, 3.226. Phil. 324. Haid. 2.441. Leon. 705.
Occurs in grains of various sizes. No cleavage. Fracture hackly. Hard. 4.0, 4.5. Sp.gr. 17.332. Opaque. Lustre metallic. Colour steel-grey. Streak shining.
Found in Peru, Brazil, and lately in Russia.

PLURANIUM, P.M. and An. 2.391, 5.234.
A metal said to have been discovered in the Russian Platina by Professor Osann of Dorpat.

POLYHALLITE, No. 538.
Phil. 199. Haid. 3.141. Leon. 769. E.J.S. 7.246.
Occurs crystallized and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = about 115°. Cleavage indistinct, parallel to M,M′. Fracture uneven. Hard. 2.5. Sp.gr. 2.73, 2.77. Opaque. Lustre resinous. Colour pale flesh-red, sometimes yellowish.
Found at Ischel in Upper Austria.

POONAHLITE, No. 369.
P.M. and An. 10.109.
Occurs in long slender crystals accompanying Apophyllite and Stilbite.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 92° 20′. Fracture uneven. Transparent, translucent. Lustre vitreous. Colourless, white.

Found at Poonah in the East Indies.

POTASH.

Nitrate of Potash.

a. NITRE. *Saltpetre*, No. 517.

Haüy, 2.177. Phil. 189. Haid. 2.34. Leon. 247.

Occurs in crusts and capillary fibres, on or near the surface of the earth, and in old walls, &c. Hard. 2.0. Sp.gr. 1.93. Transparent, translucent. Lustre of the fractured surface vitreous. Colour white, sometimes yellowish. Taste saline and cool.

Found in most parts of the World.

Sulphate of Potash.

a. BERNHARDITE, No. 524.

Haüy, 2.187. Haid. 3.159. Leon. 271.

Occurs at Mount Vesuvius in small white tubercular or globular masses on lava. Hard. 2.5, 3.0. Sp.gr. 1.737. Translucent. Lustre of the fractured surface vitreous.

PREHNITE, No. 222.

Koupholite when in very thin crystals.

Haüy, 2.603. Phil. 36. Haid. 2.217. Leon. 470.

Occurs in attached and aggregated crystals and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 99° 50′. Cleavage distinct, parallel to P, less so parallel to the lateral planes. Fracture uneven. Hard. 6.0, 7.0. Sp.gr. 2.926. Transparent, translucent. Lustre vitreous. Colour white, grey, yellow, green of various shades. Streak white.

Massive varieties, globular, botryoidal, nodular, stalactitic. Structure broad fibrous. Amorphous, structure granular, compact. Surfaces rough, drusy.

Found originally at the Cape of Good Hope, and since at many places in Europe, America, and Asia.

PUMICE, No. 247.

Phil. 133. Haid. 2.337. Leon. 411.

Occurs massive. Structure fibrous, and very porous. From its porous structure it floats on water. Translucent, opaque. Lustre of some varieties vitreous, but generally pearly. Colour grey, sometimes brownish or yellowish.

Found principally in the Lipari Islands.

See OBSIDIAN.

PYRALLOLITE, No. 166.

Phil. 68. Haid. 3.141. Leon. 512.

Occurs crystallized and massive. Cleavage parallel to the lateral planes of a prism of about 94° 36′. Fracture earthy. Hard. 3.5, 4.0. Sp.gr. 2.55, 2.60. Translucent, opaque. Lustre resinous. Colour white, occasionally greenish or yellowish.

Massive variety, structure fibrous, granular.

Found at Pargas in Finland.

PYRARGILLITE, No. 370.

Occurs in bluish and brownish-black amorphous masses, in a felspar or granitic rock in Finland.

PYROPHYLLITE, No. 255.

Formerly known as *Radiated Talc*, but newly named on account of its ready exfoliation on exposure to heat.

PYROSMALITE, No. 282.

Phil. 235. Haid. 3.143. Leon. 772.

Occurs in attached and imbedded hexagonal prisms.

Primary form a Rhomboid. CRYST. fig. 106. Cleavage distinct perpendicular to the axis, indistinct parallel to the planes of the prism. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 3.08. Transparent, opaque. Lustre of the transparent variety, vitreous, of the opaque, pearly on the cleavage surface. Colour greyish-green. Streak pale.

Found at Nordmark in Sweden.

PYROXENE. *Alalite. Baikalite. Diopside. Fassaite. Malacolite. Mussite. Pyrgom. Sahlite*, No. 268 to 272.

Haüy, 2.407. Phil. 58. Haid. 2.268. Leon. 503.

Occurs in attached and imbedded crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 105° 45′. M,M′ = 87° 5′. Cleavage parallel to the lateral planes and to both the diagonals. Fracture conchoidal, uneven. Hard. 5.0, 6.0. Sp.gr. 3.23, 3.35. Transparent to opaque. Lustre vitreous, vitreo-resinous. Colour white, grey, black, brown, yellow, green, of many shades. Streak paler colour.

Massive varieties, amorphous. Structure granular, columnar, parallel, and radiating; laminar.

Found in most basaltic rocks, in lava, and in the older rocks in most parts of the World.

RADIOLITE? No. 224.

E.J.S. 10.370.

The notice referred to is that of an analysis by Hunefeld of a substance called Radiolite, unaccompanied by any description or indication of locality. A specimen in the writer's possession, so named we believe by Esmark, exactly resembles the fibrous Mineral from Norway named *Bergmannite*. But whether this is the Mineral analyzed by Hunefeld is uncertain.

RAZOUMOFFSKIN, No. 371.

An. 4.215. 7.62.

A white powder discovered by Lentz in the clefts of quartz rocks in Silesia. In vol. iv. of the *Annals of Phil.* it is said to be composed of *silica, alumina, potash and water*; and in vol. vii. it is said to contain *silica, magnesia, and carbonic acid.* Hence two different Minerals have passed under this name.

RHODIUM. A brittle metal found by Dr. Wollaston in combination with native platina as an alloy.

RHUTENIUM. P.M. and An. 2.391. 5.233.

A metal said to have been discovered in the Russian platina by Professor Osann of Dorpat.

SAPHIRINE, No. 313.

Leon. 775.

Occurs in thin crystalline plates, separated by plates of mica. Fracture uneven. Hard. 7.0, 8.0. Sp.gr. 3.42. Translucent. Lustre vitreous. Colour blue, sometimes greenish. Streak white.

Found in Greenland.

SARCOLITE, No. 372.

P.M. and An. 10.189.

Occurs in attached crystals.

Primary form a Square prism. CRYST. fig. 61. Trans-

parent, translucent. Lustre vitreous. Colour white, and pale flesh-red.

Found in cavities in the masses ejected from Vesuvius.

Red *Analcime* and *Gmelinite* have incorrectly passed under this name merely on account of their colour.

SCAPOLITE. *Paranthine. Wernerite. Chelmsfordite,* No. 235.

Haüy, 2.586. Phil. 137. Haid. 2.264. Leon. 474.

Occurs in attached and imbedded crystals and mas-

Primary form a Square prism. CRYST. fig. 61. Frequently decomposed and dull on the surface. Cleavage parallel to the primary planes and both the diagonals. Fracture uneven. Hard. 5.0, 5.5. Sp.gr. 2.72. Translucent, opaque. Lustre vitreous. Colour white, grey, green, red.

Found in Norway, Sweden, Finland, Greenland, and in North America.

Meionite, No. 236. Generally in transparent crystals from Vesuvius.

SCHEELIUM.

a. OXIDE OF SCHEELIUM. *Scheelic Acid? Tungstic Acid?* No. 412.

Phil. 254.

Occurs massive, with some appearance of crystalline form. Fracture conchoidal. Sp.gr. 6.0. Translucent. Lustre adamantine. Colour yellow of different shades, sometimes greyish. Resembles sulphur in appearance. Inodorous. Tasteless. Insoluble in acids.

Found in quartz in a mine near Baltimore? North America.

SCHILLER SPAR. *Diallage Metalloide.* No. 287.

Haüy, 2.455. Phil. 71. Haid. 2.206. Leon. 517.

Occurs in crystalline plates and small aggregated crystals generally in serpentine. Cleavage parallel to the lateral planes and to both the diagonals of a rhombic prism of about 93° 30′. The angle of 135° to 140° quoted by Haidinger is evidently the inclination of a *primary* to a *diagonal* plane, which is 136° 15′. Fracture uneven, scarcely observable. Hard. 3.5, 4.0. Sp.gr. 2.69. Nearly opaque. Lustre pearly metallic. Colour yellowish and blackish green.

Found at Baste in the Hartz, at Zöbliz in Saxony, and a few other places.

SCHOARITE, No. 529.

Leon. 258.

This Mineral is said to be fibrous, and composed of 10 parts of silex and 90 of sulphate of barytes, *and to be soluble in sulphuric acid.*

Its professed locality is Carlisle, in the State of New York, North America.

SELENIUM, No. 45.

Occurs as a red coating on sulphur, and sometimes in small globular and botryoidal shapes, with a smooth and bright surface. Fracture conchoidal. Translucent. Lustre vitreous. Colour pale dull red.

Found in the Lipari Islands.

SIDEROCLEPTE, No. 373.

Gal. 273.

Soft. Translucent. Lustre greasy. Colour yellowish-green.

Found in the lavas of the extinct volcanoes of Brisgau.

SULPHURET OF SELENIUM, No. 110.

E.P.J. 13.190. Leon. 599.

Found in the Lipari Islands, disposed in layers, and of a brownish-yellow colour.

SILICA.

Haüy, 2.228. Phil. 1. Haid. 2.321. Leon. 372.

The differences of structure, hardness, specific gravity, mixture with foreign matter, and other characters belonging to this species, are so numerous as to render any single description inapplicable to all its varieties. And the intimate connection of some of these with others, into which they appear to pass by insensible degrees, as that of brittle opal into tough calcedony, renders it equally impracticable to define with precision their respective limits. It will, however, be convenient to divide the species first into *anhydrous*, which we simply term *quartz*, and *hydrous quartz;* and each of these into smaller subdivisions.

QUARTZ, No. 154.

a. The structure crystalline.

1. *Attached, imbedded, and aggregated crystals.*

Colourless, transparent. *Rock crystal.*

Coloured, and of various degrees of transparency and translucency.

White.

Grey.

Black.

Brown. *Smoky quartz.*

Red. *Compostella quartz.*

Yellow, transparent.

  nearly opaque. *Eisen Kiesel.*

Green, transparent.

  nearly opaque. *Prase.*

Blue, translucent. *Siderite.*

Purple. *Amethyst.*

Primary form a Rhomboid. P,P′=94° 15′. Cleavage parallel to the planes of the hexagonal prism and pyramids of the ordinary crystals. Fracture conchoidal. Hard. 7.0. Sp.gr. 2.69. Transparent to opaque. Lustre vitreous, in some varieties resinous. Colour of almost every variety.

2. *Amorphous.*

Colourless, transparent. *Rock crystal.*

Slightly bluish pale grey. *Milky quartz.*

Slightly greyish with little lustre. *Fat quartz.*

Pale red. *Rose quartz.*

Pale green, a variety of *Amethyst.*

Pale brownish-red, and greenish-grey, slightly coloured, penetrated by Amianthus. *Catseye.*

Blue. *Siderite.*

Containing minute fissures or scales of mica which reflect many brilliant points of light. *Avanturine.*

3. *Massive aggregations of particles in which the crystalline structure is apparent.*

Fibrous, the fibres parallel or divergent.

Granular, the grains varying in size, and cohering with different degrees of force, or being loose in the form of sand.

b. The crystalline structure of the particles not apparent.

Chalcedony. Botryoidal, stalactitic, reniform, nodu-

lar, amorphous, and sometimes in pseudomorphous crystals of the forms of carbonate of lime, (Hornstone,) and of Datholite. (Haytorite.) The nodular varieties are

Onyx, when composed of flat layers or bands of different colours.

Agate, when the bands are concentrically curved.

Other varieties are

Sard, brownish-yellow.

Plasma, dark green, translucent.

Chrysoprase, when pale green.

Carnelian, when white, or brownish or yellowish-red.

Heliotrope, dark green spotted with red, opaque.

Flint, in nodular and tabular masses of various shades of black and grey, and of other colours.

Mixed with variously coloured clays and other extraneous matter, and generally opaque.

Jasper, principally red, yellow, brown, and green of many shades.

Flinty slate. Basanite Touchstone. Colour dark greyish-black.

HYDROUS QUARTZ, No. 155.

Occurs nodular and amorphous.

OPAL distinguished as

Precious, when it presents iridescent colours.

Fire opal, when the internal reflection is bright red.

Hydrophane, when transparency and the colours of the precious opal may be produced by immersion in water. *Appendix*.

Common opal, when the colours, which are very various, are simple.

Semi-opal, when it is dull and opaque.

Wood opal, showing the woody structure.

Cacholong, white opaque opal.

Opal jasper, if mixed with much foreign matter.

Menilite, opaque and brown.

Hyalite, *Fiorite*, in small globular and botryoidal forms.

Geyserite. *Silicious sinter*, No. 159. *Silicious Deposits from the hotsprings in Iceland and elsewhere.*

Structure compact, resembling opal, to fine granular and earthy.

HYDROSILICITE, No. 156.

Appendix to Quartz.

P.M. N.S. 3.71.

Occurs in amorphous masses in serpentine. Fracture even. Soft. Translucent. Dull. Colour white. Feels greasy.

Found at Frankenberg in Silesia, accompanying chrysoprase, opal, and pimelite.

KONILITE, No. 157.

Phil. 207. Leon. 753.

Occurs in the form of a loose white powder in some of the amygdaloids in the Highlands of Scotland and some of the Western Islands. It appears from analysis to be nearly pure silex, but its ready fusibility into a transparent colourless bead induced Dr. Macculloch to suppose that it contained some other matter besides a small portion of lime which easily separated from it.

TRIPOLI, and POLISHING SLATE, No. 158.

Leon. 785.

These appear to be nearly similar compounds of silica in a finely divided state, with small proportions of alumina and oxide of iron.

They are massive, earthy, friable, and of a greyish, brownish, or yellowish colour.

Found in France, Italy, and some parts of Germany.

SILVER.

Stibiuret of Silver.

a. ANTIMONIAL SILVER, No. 26.

Haüy, 3.258. Phil. 236. Haid. 2.427. Leon. 685.

Occurs crystallized, granular, and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ about 120°. Cleavage parallel to the terminal plane and short diagonal of the prism. Fracture uneven. Hard. 3.5. Sp.gr. 9.44, 9.82. Opaque. Lustre metallic. Colour silver-white. Streak the same.

Massive varieties, amorphous, structure granular, foliated.

Found in the Hartz, in Salzburg, and at Guadalcanal in Spain.

Arsenical Stibiuret of Silver frequently accompanies the preceding, of which it is considered a variety containing a mixture of arsenic.

Carbonate of Silver.

a. SELBITE, No. 459.

Haüy, 3.290. Phil. 295. Leon. 702.

Occurs massive and disseminated in veins traversing granite. Structure fine granular. Fracture uneven. Soft. Heavy. Opaque. Lustre metallic. Colour greyish-black.

Found at Altwolfatch in the Black Forest.

Chloride of Silver.

a. LAXMANNITE. *Horn Silver. Muriate of Silver*, No. 67.

Haüy, 3.292. Phil. 295. Haid. 2.154. Leon. 581.

Occurs crystallized and massive.

Primary form a Cube. CRYST. fig. 56. No cleavage. Fracture uneven. Hard. 1.0, 1.5. Sp.gr. 5.55. Translucent. Lustre resinous, bright. Colour grey, yellow, green, blue of different shades, mostly dull. Streak shining. Sectile.

Found with other ores of silver in several parts of Europe and America.

Iodide of Silver.

a. HERRERALITE, No. 57.

Nuevo Systema Mineral, por Del Rio, p. 8.

Structure lamellar. Soft. Externally white, internally yellowish.

Found in serpentine at Albarradon in the State of Zacatecas, Mexico.

Native Silver.

a. SILVER, No. 11.

Haüy, 3.249. Phil. 285. Haid. 2.433. Leon. 699.

Occurs crystallized, dendritic, capillary, and massive.

Primary form a Cube. CRYST. fig. 56. No cleavage. Fracture hackly. Hard. 2.5. 3.0. Sp gr. 10.473. Opaque. Lustre metallic. Colour white. Streak shining.

Massive varieties, amorphous, laminar.

Found in many different places in Europe and America.

b. *Auriferous Native Silver* does not appear to form a distinct chemical species, but differs in the proportions of gold and silver in different specimens.

Seleniuret of Silver and Copper.

a. EUCAIRITE, No. 54.

Mineralogy

Haüy, 3.470. Phil. 294. Haid. 3.94. Leon. 593.
Occurs in small granular masses in a serpentine rock. Soft. Opaque. Lustre metallic. Colour greyish-white.
Found in Sweden.

Sulphuret of Silver.

a. HENKELITE. *Silver Glance*, No. 88.
Haüy, 3.265. Phil. 288. Haid. 3.11. Leon. 635.
Occurs in attached and aggregated crystals and massive.
Primary form a Cube. CRYST. fig. 65. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 7.196. Opaque. Lustre metallic. Colour lead-grey, sometimes blackish from tarnish.
Massive varieties, amorphous, laminar.
Found in most silver mines.

Sulphuret of Silver and Iron?

a. STERNBERGITE, No. 91. *Flexible Sulphuret of Silver of Bournon.* Cat. 209.
E.J S. 7.242. Leon. 779.
Occurs in attached crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 119° 30′. Cleavage distinct parallel to the terminal plane. The laminæ very flexible. Hard. 1.0, 1.5. Sp.gr. 4.215. Opaque. Lustre metallic. Colour dark brown, often with a blue tarnish. Streak black.
Found at Joachimsthal in Bohemia.

Sulphuret of Silver and Antimony.

RED SILVER.

Rhomboidal.

a. BRAARDITE, No. 104.
Haüy, 3.269. Phil. 291. Haid. 3 38. Leon. 610.
Occurs in attached crystals and massive.
Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 108° 30′. Cleavage parallel to the primary planes, generally indistinct. Fracture conchoidal. Hard. 2.0, 2.5. Sp gr. 5.846. Translucent. Opaque. Lustre adamantine. Colour red, of different shades, frequently dark and blackish. Streak red.
Massive varieties, amorphous, structure granular, compact.
Found in many parts of Europe and America.

Oblique Prismatic.

b. MIARGYRITE, No. 105.
Haid. 3.12.
Occurs in attached crystals.
Primary form an Oblique rhombic prism. CRYST. fig. 83. M,M′ = 86° 4′. P,*h*, fig. 91, 101° 6′. Cleavage imperfect. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 5.234. Nearly opaque. Lustre bright metallic. Colour iron-black. Streak dark red.
Found near Freiberg in Saxony.

Right Prismatic.

c. POLYBASITE. *Brittle Silver*, No. 106.
Haüy, 3.280. Phil. 390. Haid. 3.27. Leon. 638.
Occurs in attached and aggregated crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 111° 8′. Haid. Cleavage imperfect. Fracture uneven. Hard. 2.0, 2.5. Sp.gr. 6.269. Translucent. Opaque. Lustre metallic. Colour iron-black.
Found in Saxony, Bohemia, and other parts of Europe, and in Mexico and Peru.
Among the numerous specimens named Brittle Silver in the Mineral collections in this Country, we have not observed one agreeing in crystalline form with the above description.

Sulphuret of Silver and Antimony.

a. ROMELITE. *Mine d'Argent grise Antimoniale*, No. 103.
De l'Isle, 3.54. Phil. 290. Haid. 3.30. Leon. 685.
Occurs in attached crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 100°. Phil. Cleavage parallel to the lateral planes. Sp.gr. 5.5. Opaque. Lustre metallic. Colour nearly silver-white.
Found near Freiberg.

Sulphuret of Silver and Copper.

a. SILVERKUPFERGLANE, No. 89.
Phil. 293. Haid. 3.73. Kirwan, 2.121.
Occurs massive. Compact. Fracture flat conchoidal. Soft. Sp.gr. 6.255. Opaque. Lustre metallic. Colour dark lead-grey. Streak shining.
Found in Siberia.

Sulphuret of Silver, Lead, and Bismuth.

a. BISMUTHIC SILVER, No. 90.
Phil. 294. Haid. 3.78. Leon. 618.
Occurs in acicular crystals and massive.
Fracture uneven. Opaque. Colour when first broken light lead-grey, but liable to tarnish.
Massive varieties, amorphous, structure compact.
Found at Shapbach in Baden, in a bed of gneiss.

Sulpho-telluret of Silver and Bismuth.

a. MOLYBDIC SILVER. *Molybdan Silver*, No. 21.
Phil. 287. Haid. 3.127. Leon. 589.
Occurs in small laminated masses at Deutsch Pilsen near Grard, and resembles the Sulpho-telluret of Bismuth, but is said to be composed of sulphur, bismuth, tellurium, and silver. It appears, however, to be an uncertain species.

SODA.

Borate of Soda.

a. BORAX. *Tincal*, No. 424.
Haüy, 2.200. Phil. 192. Haid. 2.52. Leon. 148.
Occurs in single crystals and massive.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 101° 30′. M,M′ = 86° 40′. Cleavage parallel to the lateral planes and both diagonals. Fracture conchoidal. Hard. 2.0, 2.5. Sp.gr. 1.716. Transparent, translucent. Lustre resinous. Colour slightly greyish, greenish, or bluish-white. Streak white.
Found chiefly in a lake in Thibet, and also in Persia and in South America.

Carbonate of Soda.

a. *Oblique Rhombic*, No. 432.
Haüy, 2.207. Phil. 190. Haid. 2.27. Leon. 149.
Occurs crystallized, massive, and in powder.
Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 108° 45′. M,M′ = 76° 12′. Levy. Cleavage parallel to the primary planes and oblique diagonal. Fracture conchoidal. Hard. 1.0, 1.5. Sp.gr. 1.423. Transparent, tranlucent. Lustre vitreous. Colour white, sometimes yellowish or greyish. Streak white. Very efflorescent.
Massive varieties, structure fibrous, granular.
Found abundantly in Hungary and the natron lakes of Egypt, and in some other places.

b. Right Rhombic, No. 433.
Haid. 2.29.
Occurs in crystals lining cavities of the massive varieties of the preceding species.
Primary form a Right rhombic prism. Cryst. fig. 71. M,M′ = 107° 50′. Cleavage indistinct. Fracture conchoidal. Hard. 1.5. Sp.gr. 1.562. Transparent, translucent. Lustre vitreous. Colour white, sometimes yellowish. Streak white. Less efflorescent than the preceding species.

c. Trona, No. 434.
Phil. 190. Haid. 3.164. Leon. 149.
Occurs in crystalline coats, with a fibrous structure.
Primary form an Oblique rhombic prism. Cryst. fig. 83. Measurements uncertain. Cleavage parallel to P, distinct. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 2.112. Transparent, translucent. Lustre vitreous. Colour white, sometimes yellowish. Streak white. Does not effloresce.
Found on the banks of lakes in the Kingdom of Fezzan in Africa.

d. Bicarbonate of Soda? No. 435.
N.J. 35. 48.
Occurs in strata of two to six inches thick on a bed of clay containing muriate of soda. Structure granular. Colour yellowish-grey, does not effloresce.
Found near Buenos Ayres.

Carbonate of Soda and Lime.

a. Gay Lussite, No. 436.
E.J.S. 5.372. P.M. and An. 1.263.
Occurs in imbedded crystals.
Primary form a Right rhombic prism. Cryst. fig. 71. M,M′ = 68° 50′. Cleavage parallel to the lateral planes distinct; less so parallel to the terminal plane. Fracture conchoidal. Hard. 2.5. Sp gr. 1.93, 1.99. Transparent. Lustre vitreous. Colourless.
Found in a thin stratum of soft clay covering a bed of carbonate of soda, called *Urao*, at the bottom of a lake near Lagunilla, a day's journey South-West of Merida in Columbia.

b. Barruelite, No. 437.
P.M. and An. 7.389.
Occurs in crystalline masses. Cleavage distinct, parallel to the planes of a rhomboid, supposed to be similar to that of carbonate of lime. Hard. 3.5. Sp.gr. 2.921. Transparent. Lustre vitreous. Colour not described.
Locality unknown.
Differs from Gay Lussite in the proportions of its constituent elements. But the accuracy of the analysis appears to be questioned by Berzelius.

Chloride of Sodium.

Rock Salt, No. 59.
Haüy, 2.191. Phil. 193. Haid. 2.36. Leon. 584.
Occurs in solution in water, and massive. Structure crystalline, fibrous.
Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the primary planes. Fracture conchoidal. Hard. 2.0. Sp.gr. 2.257. Transparent, translucent. Lustre vitreous, rather dull. Colour white, grey, red, yellow, blue. Streak white. Taste saline.
Found abundantly in Europe, Asia, Africa, and America. The great salt deposits in this Country are Northwich in Cheshire, and Droitwich in Worcestershire.

Nitrate of Soda.

a. Riverolite, No. 518.
Haüy, 2.214. Phil. 191. Haid. 3.132. Leon. 246.
Occurs with clay in beds of different thickness.
Primary form a Rhomboid. Cryst. fig. 106. P,P′ = 106° 33′. Haid. Cleavage parallel to the primary planes. Fracture conchoidal. Hard. 1.5, 2.0. Sp.gr. 2.096. Transparent. Lustre vitreous. Colour white. Streak white. Taste cool.
Found crystallized in the district of Atacama in Peru.

Sulphate of Soda.

a. Glauber Salt, No. 525.
Haüy, 2.189. Phil. 191. Haid. 2.31. Leon. 125.
Occurs in solution in water, and as an efflorescence on soil and other surfaces.
Primary form an Oblique rhombic prism. Cryst. fig. 83. P,M = 101° 20′. M,M′ = 80° 24′. Cleavage parallel to the terminal planes. Fracture conchoidal. Hard. 1.5, 2.0. Sp gr. 1.48. Transparent, translucent. Lustre vitreous. Colour white. Streak white. Taste cool, bitter.
Found in several places in and out of Europe.

Anhydrous Sulphate of Soda.

a. Thenardite, No. 526.
E.J.S. 6.182. An. n.s. 12.313.
Occurs crystallized.
Primary form a Right rhombic prism. Cryst. fig 71. M,M′ about 125°. Cleavage parallel to the primary planes. Sp.gr. about 2.73. Translucent, opaque. Soluble in water.
Found at Espertines near Madrid.

Sulphate of Soda and Lime.

a. Glauberite. *Brongniartin*, No. 534.
Haüy, 2.215. Phil. 198. Haid. 2.54. Leon. 270.
Occurs in imbedded crystals in rock salt.
Primary form an Oblique rhombic prism. Cryst. fig. 83. P,M = 104° 15′. M,M′ = 83° 20′. Cleavage parallel to P and M. Fracture conchoidal. Hard. 2.5, 3.0. Sp.gr. 2.807. Transparent, translucent, but becomes opaque after immersion in water. Lustre vitreous. Colour yellowish and greyish-white. Streak white. Taste slightly saline.
Found at Ocaña in New Castile, and at Aussee in Upper Austria.

Sulphate of Soda and Magnesia.

a. Reussite, No. 536.
A salt said to consist of about two-thirds sulphate of soda, and one-third sulphate of magnesia, but of which we do not find any published description.

Sodalite, No. 240.
Haüy, 3.59. Phil. 127. Haid. 2.226. Leon. 461.
Occurs in attached and aggregated crystals and massive.
Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the planes of the Rhombic dodecahedron. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 2.3. Translucent. Lustre vitreous. Colour greenish-grey and greenish and greyish-white. Streak white.
Massive varieties, amorphous. Structure granular, compact. Minerals from Greenland, Siberia, and Vesuvius have passed under this name, but it is doubtful whether they all belong to the same species.

Somervillite. *Humboldtilite of Manticelli*, No. 374.

Q.J. 16.274. Haid. 3.154. Leon. 484.
Occurs in attached crystals.
Primary form a Square prism. CRYST. fig. 65. P,a = 147° 5′. Cleavage perpendicular to the axis, very distinct. Fracture uneven. Transparent, translucent. Lustre vitreous. Colour dull pale brownish-yellow.
Found in the cavities of matter ejected from Vesuvius.

SORDAWALITE, No. 309.
Phil. 210. Haid. 3.155. Leon. 799.
Occurs massive. Structure compact. Fracture conchoidal. Hard. 5.0. Sp.gr. 2.53. Opaque. Lustre vitreo-metallic. Colour greenish or greyish-black.
Found near Sordawala in Finland.

SPHÆRULITE, No. 248.
Phil. 209. Haid. 3.155. Leon. 780.
Occurs in small spheroidal and botryoidal masses imbedded in pearlsone and pitchstone. Structure fibrous, compact. Hard. 7.0, 7.5. Sp.gr. 2.4, 2.52. Opaque. Dull. Colour grey, brown, red, yellow of various shades.
Found in Hungary, Saxony, Iceland, and Scotland.

SPINELLANE, No. 566.
Haüy, 4.507. Phil. 127. Haid. 3.156. Leon. 459.
Occurs in imbedded dodecahedral crystals in a rock of glassy felspar.
Primary form a Cube. CRYST. fig. 56. Cleavage distinct, parallel to the planes of the Rhombic dodecahedron. Fracture uneven. Hard. 5.5, 6.0. Sp.gr. 2.28. Translucent, opaque. Lustre vitreo-resinous. Colour grey, greyish-black, brown.
Found at the Lake of Loach. This might have been called Sodalite with as much propriety as the variety from Vesuvius.

SPINELLE. *Pleonaste. Candite. Balas Ruby*, No. 147.
Haüy, 2.166. Phil. 90. Haid. 2.295. Leon. 544.
Occurs in loose and imbedded octahedral crystals.
Primary form a Cube. CRYST. fig. 56. Cleavage indistinct. Fracture conchoidal. Hard. 8.0. Sp gr. 3.5, 3.7. Transparent, translucent. Lustre vitreous. Colour black, brown, red, yellow, green, blue, violet. Streak white.
Found in loose crystals in Ceylon, and imbedded in carbonate of lime in Sweden and North America.

SPODUMENE. *Triphane*, No. 230.
Haüy, 3.134. Phil. 142. Haid. 2.216. Leon. 433.
Occurs in imbedded crystalline masses of various sizes.
Cleavage parallel to the lateral planes and great diagonal of a Rhombic prism of about 93°. Fracture uneven. Hard. 6.5, 7.0. Sp.gr. 3.17, 3.19. Translucent. Lustre pearly on the cleavage planes. Colour white, sometimes greyish and greenish, and greyish-green. Streak white.
Found in Sweden, the Tyrol, Ireland, and in North America.

Soda Spodumene, No. 231.
Lustre more vitreous than the preceding.

STAUROLITE. *Grenatite. Staurotide*, No. 321.
Haüy, 2.338. Phil. 82. Haid. 2.366. Leon. 409.
Occurs in imbedded crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 129° 20′. Phil. Cleavage parallel to the lateral planes and both diagonals. Fracture uneven. Hard. 7.0, 7.5. Sp.gr. 3.3, 3.72. Transparent, translucent. Lustre vitreo-resinous. Colour dark brownish-red. Streak white.
Found in France, Spain, Portugal, and some other parts of Europe, and in North America.

STILBITE, No. 213.
Haüy, 3.155. Phil. 37. Haid. 2.239. Leon. 193.
Occurs in attached and variously aggregated crystals.
Primary form a Right rhombic prism. M,M′ = 94° 11′. Levy. Cleavage parallel to both the diagonals. Fracture uneven. Hard. 3.5, 4.0. Sp.gr. 2.16, 2.5. Transparent, translucent. Lustre vitreous. Colour white, brown, red, yellow. Streak white.
The aggregated crystals are sometimes fasciculated.
Found abundantly in Iceland and the Faroe Islands, and generally in trap rocks.

STRONTIA.

Carbonate of Strontia.

STRONTIANITE, No. 439.
Haüy, 2.43. Phil. 186. Haid. 2.116. Leon. 328.
Occurs in acicular, rarely in tabular crystals, and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 117° 30′. Cleavage distinct parallel to M,M′. Fracture uneven. Hard. 3.5. Sp.gr. 3.6, 3.67. Transparent, translucent. Lustre vitreous. Colour white, grey, pale, brown, and green. Streak white.
Massive varieties, globular, amorphous. Structure fibrous, with a pearly lustre, rarely granular.
Found at Strontian in Scotland, Braunsdorf in Saxony, Leogang in Salzburg, and in Peru.

Barytiferous Carbonate of Strontia.

STROMNITE, No. 440.
Haid. 3.159.
Occurs massive, in veins in clay slate.
Structure fibrous with traces of crystallization. Hard. 3.5. Sp.gr. 3.7. Translucent. Lustre inclining to pearly. Colour yellowish and greyish-white.
Found at Stromness in Orkney.

Sulphate of Strontia.

CELESTINE, No. 530.
Haüy, 2.30. Phil. 187. Haid. 2.126. Leon. 262.
Occurs crystallized and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 104°. Cleavage parallel to the primary planes. Fracture uneven. Hard. 3.0, 3.5. Sp.gr. 3.6, 3.86. Transparent, translucent. Lustre vitreous, pearly on the cleavage surfaces. Colour white, pale blue, and red of different shades.
Massive varieties, nodular, tabular, amorphous. Structure columnar, fibrous, granular.
Found in Sicily, at Bex in Swisserland, at Lake Erie, North America, in the Tyrol, and some other places, and massive near Bristol.

Sulphate of Strontia and Barytes.

GRUNERITE. *Radiated Celestine*, No. 531.
E.P.J. 11.329. Leon. 266.
Occurs in beds in a coarse limestone. Structure radiated. Hard. 3.0, 3.5. Sp.gr. 3.7619. Translucent. Lustre vitreous. Colour white, occasionally with a shade of blue.
Found at Norten near Hanover.

SULPHUR.

a. NATIVE SULPHUR, No. 69.
Haüy, 4.407. Phil. 360. Haid. 3.52. Leon. 595.
Occurs in attached crystals and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 101° 59′. Haid. Cleavage indistinct. Fracture conchoidal. Hard. 1.5, 2.5. Sp.gr. 2.072. Transparent, translucent. Lustre resinous. Colour yellow, greenish-grey. Streak paler.
Massive varieties, stalactitic, of various shapes. Structure compact. Amorphous, structure crystalline, granular, compact.
Found in beds in primitive and secondary rocks in several parts of Europe, and generally in volcanic Countries. Most of the sulphur of commerce comes from Solfatara near Naples.

b. SULPHURIC ACID, No 521.
Phil. 144. Haid. 2.23.
Occurs as a gas issuing from active volcanoes, also in a fluid state in their neighbourhood, and in a concrete form in grottos and caves in the mountain Raccolino, near Sienna, and in some other volcanic districts.
Odour of the gas pungent; taste of the fluid and solid strongly acid and burning.

TACHYLITE, No. 311.
E.N.P.J. 1.364. Leon. 781.
Occurs massive and in plates.
No cleavage. Fracture small, conchoidal. Hard. 6.5. Sp.gr. 2.50, 2.54. Translucent, opaque. Lustre vitreous, vitreo-resinous. Colour brownish and greenish-black. Streak dark grey. Resembles Obsidian.
Found at Süsabühl, near Gottingen.

TALC. *Potstone*, No. 254.
Haüy, 2.489. Phil. 116, 117, 120. Haid. 2.193. Leon. 444.
Occurs in attached and aggregated hexagonal crystals and massive.
Primary form a Rhomboid. CRYST. fig. 106. Cleavage distinct, perpendicular to the axis. Hard. 1.0, 1.5. Sp.gr. 2.713. Translucent. Lustre pearly. Colour white, greyish, and green of many shades. Streak the same.
Massive varieties, granular, earthy.
Found in all parts of the World.
It is probable that several distinct species of Minerals have passed under this name.

TANTALITE. *Columbite*, No. 402 to 408.
Haüy, 4.387. Phil. 269. Haid. 2 390. Leon. 349.
Occurs in attached and imbedded crystals and massive.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 104° nearly. Fracture uneven. Hard. 6.0. Sp.gr. 6.038. Opaque. Lustre imperfect metallic. Colour greyish-black.
Massive variety, nodular, amorphous. Structure granular, compact.
Found in Finland, Sweden, Bavaria, and North America.

TAUTOLITE, No. 375.
E.J.S. 8.181.
Occurs crystallized in the volcanic rocks at Lake Loach.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 109° 48′. Cleavage parallel to M and the greater diagonal. Fracture uneven. Hard. 6.5, 7.0. Sp.gr. 3.865. Opaque. Lustre vitreous. Colour black. Streak grey.

TELLURIUM.

a. NATIVE TELLURIUM, No. 19.
Haüy, 4.379. Phil. 326. Haid. 2.421. Leon. 691.
Occurs in minute attached Hexagonal prisms and massive.
Primary form a Rhomboid. CRYST. fig. 106.
Massive variety, structure granular. Hard. 2.0, 2.5. Sp.gr. 6.115. Opaque. Lustre metallic. Colour tin-white.
Found at Facebay in Transylvania.

b. GRAPHIC TELLURIUM. *Auro-argentiferous Tellurium*, No. 24.
Haüy, 4.380. Phil. 327. Haid. 3.21. Leon. 690.
Occurs in attached flattened crystals.
Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 107° 44′. Phil. Fracture uneven. Hard. 1.5, 2.0. Sp.gr. 5.72. Opaque. Lustre metallic. Colour steel-grey.
Found only in Transylvania.

c. YELLOW TELLURIUM, No. 23.
Phil. 328. Haid. 3.171. Leon. 691.
Occurs in imbedded crystalline laminæ. Lustre metallic. Colour silver or yellowish-white.
Found in Transylvania.

d. BLACK TELLURIUM. *Foliated Tellurium. Auro-plumbiferous Tellurium*, No. 22.
Haüy, 4.381. Phil. 328. Haid. 3.16. Leon. 689.
Occurs in attached and aggregated crystals and in imbedded foliated masses.
Primary form a Square prism. Cleaves into thin flexible laminæ parallel to the terminal plane. Hard. 1.0, 1.5. Sp.gr. 7.085. Opaque. Lustre metallic. Colour dark lead-grey.
Found in Transylvania.

THOMSONITE, No. 212.
Phil. 39. Haid. 3.162. Leon. 208.
Occurs massive. Structure large fibrous, radiated; the fibres prolonged into separate small columnar crystals in the cavities.
Primary form a Right rhombic prism. M,M′ = 90° 40′ nearly. Cleavage parallel to the two diagonals. Fracture uneven. Hard. 5.0. Sp.gr. 2.37. Transparent, translucent. Lustre vitreous. Colour white.

THORITE, No. 376.
Q.J. 6.296.
Occurs massive, and much resembles the Gadolinite of Ytterby. Fracture uneven, very brittle, full of cracks. Hard. about 5.0. Sp.gr. 4.63. Opaque. Lustre resinous, vitreous. Colour black. Streak greyish-red. Powder pale brownish-red.
Found in Syenite, on the Island of Lov-ou, near Brevig, Norway.

TIN.

Oxide of Tin.

a. TINSTONE, No. 139.
Haüy, 4.152. Phil. 250. Haid. 2.384. Leon. 354.
Occurs in attached and imbedded crystals and mas-

Primary form a Square prism. CRYST. fig 65. Cleavage parallel to the lateral planes and both diagonals. Fracture uneven. Hard. 6.0, 7.0. Sp.gr. 6.960, crystallized, 6.319, fibrous. Transparent to opaque. Lustre adamantine. Colour white, grey, black, brown, red, yellow, of various shades. Streak paler.

Massive varieties, reniform, botryoidal, (Wood tin,) structure fibrous; amorphous, structure crystalline, granular.

Found abundantly in Cornwall, Bohemia, Saxony, and in the older rocks in other Countries.

Sulphuret of Tin and Copper.

a. TIN PYRITES, No. 87.

Phil. 254. Haid. 3.163. Leon 624.

Occurs in attached crystals and massive.

Primary form not ascertained. Cleavage imperfect. Fracture uneven. Hard. 4.0. Sp.gr. 4.35. Opaque. Lustre metallic. Colour yellowish-grey. Streak black.

Found in Cornwall.

TITANIUM.

Oxide of Titanium.

a. ANATASE. *Octaedrite*, No. 386.

Haüy, 4.344. Phil. 257. Haid. 2.379. Leon. 358.

Occurs in attached and imbedded octahedral crystals.

Primary form a Square prism. CRYST. fig 65. M,*c* (fig. 68) = 158° 24′. Cleavage parallel to the terminal plane, and to those of the octahedron. Fracture indistinct. Hard. 5.5, 6.0. Sp.gr. 3.826. Transparent, translucent. Lustre adamantine. Colour white, brown, blue. Streak white.

Found in Cornwall, Dauphiny, Brazil, and a few other places.

b. RUTILE, No. 387.

Haüy, 4.333. Phil. 258. Haid. 2 376 Leon. 360.

Occurs in attached and imbedded crystals and crystalline masses.

Primary form a Square prism. CRYST. fig. 65. M,*c* (fig. 68) = 122° 45′. Cleavage parallel to the lateral planes. Fracture uneven. Hard. 6.0, 6.5. Sp.gr. 4.249. Transparent to opaque. Lustre adamantine. Colour red and reddish-brown of several shades. Streak pale brown.

Found in Brazil, North America, Spain, and other parts of Europe.

c. BROOKITE? No. 388.

An.P. 1825. Haid. 3.82. Leon. 725.

Occurs in attached crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 100°. Levy. Cleavage parallel to the lateral planes and short diagonal. Fracture uneven. Hard. 5.5, 6.0. Transparent to opaque. Lustre adamantine. Colour deep red and reddish, and yellowish-brown. Streak yellowish-white.

Found at Snowdon in Wales, in large crystals, in Dauphiny, Swisserland, and a few other places.

Silico titaniate of Lime.

a. SPHENE. *Spinthere. Semeline*, No. 394.

Haüy, 4.353. Phil. 262. Haid. 2.373. Leon. 368.

Occurs in attached and imbedded crystals and massive.

Primary form an Oblique rhombic prism. CRYST. fig. 83. P,M = 121° 30′. M,M′ = 133° 30′. Phil. Cleavage indistinct. Fracture uneven. Hard. 5.0, 5.5. Sp gr. 3.468. Transparent to opaque. Lustre adamantine to dull resinous. Colour grey, brown, yellow, green. Streak white.

Found in primitive rocks in several parts of Europe and America.

TOPAZ. *Pycnite. Pyrophysalite*, No. 516.

Haüy, 2.131. Phil. 84. Haid. 2.308. Leon. 401.

Occurs in attached, loose, and imbedded crystals, and massive.

Primary form a Right rhombic prism. M,M′ = 124° 23′. Cleavage parallel to the terminal plane distinct, to the lateral planes indistinct. Fracture uneven. Hard. 8.0. Sp.gr. 3.5. Transparent to nearly opaque. Lustre vitreous. Colour white, yellow of many shades, brownish-yellow, pink, blue, green. Streak white.

Massive variety, (Pycnite,) structure columnar.

Found in Brazil in loose crystals, and in primitive rocks in many other Countries, particularly in Siberia.

TORRELITE, No. 377.

An. N.S. 9.217. Haid. 3.164. Leon. 482. 784.

Occurs in granular masses in the Andover mine, Sussex County, New Jersey. Colour dull vermilion-red. It was at first supposed to contain cerium, but by a later analysis it appears to consist principally of silica, lime, and oxide of iron and manganese.

TOURMALINE. Black, *Electric Schorl*. Blue, *Indicolite*. Red to purple, *Rubellite. Apyrite*, No 429.

Haüy, 3.14. Phil. 139. Haid. 2.349. Leon. 446.

Occurs in attached, imbedded, and aggregated crystals.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 133° 26′. Cleavage imperfect. Fracture uneven. Hard. 7.0, 7.5. Sp.gr. 3.076. Transparent to opaque. Lustre vitreous. Colour white, grey, brown, red, yellow, green, blue.

Found in Siberia, Ceylon, Brazil, North America, and many other places.

TURNERITE, No. 378.

Phil. 382. Haid. 3.166. Leon. 786.

Occurs in attached crystals.

Primary form an Oblique rhombic prism. CRYST. fig. 83. Cleavage parallel to both diagonals of the prism. Hard. 4.5, 5.0. Transparent, translucent. Lustre vitreous. Colour yellow, sometimes brownish.

Found at Mount Sorel in Dauphiny.

The *Pictite* of Lametherie is said by Gallitzin (1802) to be the *Sphene* of Haüy. But it is described as pointed as a graver, and nearly equal to the gems in hardness, and is probably, therefore, *Axinite*.

URANIUM.

Oxide of Uranium.

a. PITCHBLENDE. *Uran-pitch-ore*, No. 138.

Haüy, 4.316. Phil. 267. Haid. 2 393. Leon. 565.

Occurs in reniform and amorphous masses. Structure granular, compact. Fracture uneven. Hard. 5.5. Sp.gr. 6 468. Opaque. Lustre imperfect metallic. Colour greyish and brownish-black.

Found in Cornwall, but chiefly in Saxony and Bohemia.

Phosphate of Uranium.

a. URANITE. *Uran-mica*, No. 504.

Haüy, 4.319. Phil. 267. Haid. 2.182. Leon. 140.
Occurs in attached crystals.
Primary form a Square prism. Cryst. fig. 65. P,c (fig. 68) = 112° 10′. Cleavage parallel to the terminal plane very distinct. Hard. 2.0, 2.5. Sp.gr. 3.1. Transparent, translucent. Lustre adamantine. Colour yellow, greenish-yellow, and green of several shades.
Found in Cornwall, France, and some parts of Germany.
The green variety has received the name of *Chalkolite*, No. 505.

Sulphate of Uranium and Copper.

a. Johannite, No. 563.
E.J.S. n.s. 3.306. Leon. 115.
Occurs in small botryoidal concretions. Hard. 2.0, 2.5. Sp.gr. 3.191. Translucent. Lustre vitreous. Colour bright grass-green. Streak pale green. Soluble in water. Taste astringent, bitter.
Found at Joachimsthal in Bohemia.

Vargasite, No. 379.
A pale greenish Mineral found in Finland, in amorphous masses, having a small columnar structure, and so named after Count Vargas Bodemar.
No analysis or description published.

Werthite, No. 380.
A rolled mass found near St. Petersburg has been so named. Structure small, columnar. Colour pale yellowish-white.

Withamite, No. 381.
E.J.S. 2.218. Haid. 3.170. Leon. 476.
Occurs in small imbedded globular masses, composed of minute crystals, radiating from the centre, and having the form and measurements of Epidote. Hard. 6.0, 6.5 Sp.gr. 3.137. Translucent. Lustre vitreous. Colour red. Streak white.
Found at Glencoe in Scotland.

Wolkonskoit, No. 382.
Occurs massive, amorphous, structure compact. Hard. 2.5. Sp.gr. 2.213. Opaque. Nearly dull. Colour emerald-green. Streak shining. Feels greasy.
Found at Perm in Siberia.

Xanthite, No. 383.
Is said to be yellow Idocrase. Found in North America.

Xantholite, No. 384.
Found in North America. Has the appearance and form of Garnet.

Xylokryptite, No. 589.
Occurs in delicate yellow crystals in Lignite, having a fatty lustre.

Yttria.

Phosphate of Yttria.

a. Tankelite, No. 487.
E.J.S. 327. Leon. 276.
Occurs in aggregated crystals and massive.
Primary form a Square prism. Cleavage parallel to the primary planes. Fracture uneven. Hard. 4.5, 5.0. Sp.gr. 4.56. Opaque. Lustre resinous. Colour yellowish-brown. Streak pale brown.
Found near Lindernoes in Norway.

Silicate of Yttria and Iron.

a. Gadolinite. *Ytterbite*, No. 325, 326.
Haüy, 2.440. Phil. 105. Haid. 2.371. Leon. 526. 500.
Occurs in imbedded crystals and massive.
Primary form an Oblique rhombic prism. Cryst. fig. 83. P,M = 96°. M,M′ = 115°, nearly. No apparent cleavage. Fracture flat conchoidal. Hard. 6.5, 7.0. Sp.gr. 4.238. Slightly translucent. Lustre vitreo-resinous. Colour greenish-black. Streak greenish-grey.
Massive varieties, amorphous, structure compact.
Found at Ytterby, Finbo, and Broddbo in Sweden, and in Greenland.

Tantalate of Yttria, &c.

a. Yttro-tantalite, No. 399 to 401.
Haüy, 4,389. Phil. 271. Haid. 3.173. Leon. 352.
Occurs in imbedded imperfect crystals, and small amorphous masses. Cleavage in one direction. Fracture granular. Hard. 5.0, 5.5. Sp.gr. 5.4, 5.8. Opaque. Lustre vitreo-resinous. Colour black, brownish-black, yellowish-brown.
Found at Ytterby in Sweden.

Tantalate of Yttria and Cerium.

a. Fergusonite, No. 398.
Haid. 3.98. Leon. 738.
Occurs in imbedded crystals in quartz.
Primary form a Square prism. Cryst. fig. 65. Cleavage uncertain. Fracture conchoidal. Hard. 5.5, 6.0. Sp.gr. 5.838. Opaque. Lustre resino-metallic. Colour brownish-black. Streak pale brown.
Found near Cape Farewell in Greenland.

Titaniate of Yttria, Zircon, and Lime.

a. Polymignite, No. 396.
E.J.S. 3.329.
Occurs in imbedded crystals.
Primary form a Right rhombic prism. Cryst. fig. 71. M,M′ = 110° 30′ nearly. Fracture conchoidal. Hard. 6.5. Sp.gr. 4.8. Opaque. Lustre imperfect metallic. Colour black. Streak dark brown.
Found at Frederiksvärn in Norway.

Zeagonite. *Abrazite. Gismondine. Phillipsite*, No. 219.
Phil. 11. Haid. 3.171. Leon. 198.
Occurs in attached crystals, and globular crystalline masses with a fibrous structure.
Primary form unknown, probably a Right rhombic prism, the apparently Square prisms being twin crystals. Fracture conchoidal. Hard. 7.0, 7.5. Transparent to opaque. Lustre vitreous. Colour white, sometimes greyish or reddish. Streak white.
Found at Vesuvius, and frequently in trap rocks. Small crystals of zircon of a pale blue colour have come to this Country ticketed Zeagonite, and have led to an incorrect description of the crystalline form of that Mineral.

Zinc.

Aluminate of Zinc.

Automalite. *Gahnite*, No. 150.
Haüy, 2.170. Phil. 83. Haid. 2.298. Leon. 544.
Occurs in imbedded octahedral crystals, and granular masses.
Primary form a Cube. Cryst. fig. 56. Cleavage parallel to the planes of the octahedron, distinct. Fracture conchoidal. Hard. 8.0. Sp.gr. 4.232.

Slightly translucent. Lustre vitreous. Colour dull green. Streak white.

Found at Fahlun and Broddbo in Sweden, imbedded in slaty talc.

Carbonate of Zinc.

CALAMINE, No. 454.

Haüy, 4.181. Phil. 355. Haid. 2.111. Leon. 158.

Occurs crystallized and massive.

Primary form a Rhomboid. CRYST. fig. 106. P,P′ = 107° 40′. Wollaston. Cleavage parallel to the primary planes. Fracture uneven. Hard. 5.0. Sp.gr. 4.44. Translucent, opaque. Lustre vitreous. Colour white, grey, brown, green. Streak white.

Massive varieties, reniform, botryoidal, stalactitic, structure fibrous. Amorphous, structure granular, compact. Both varieties are sometimes found in an earthy state.

Found in England, France, and other places in Europe, and in America.

Red Oxide of Zinc.

a. SPARTALITE, No. 124.

Haüy, 4.179. Phil. 353. Haid. 2.380. Leon. 563.

Occurs in imbedded small nodules and massive. Cleavage parallel to all the planes of a regular hexagonal prism. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 5.43. Translucent. Lustre adamantine. Colour red. Streak orange-yellow.

Massive varieties, amorphous, structure crystalline, granular.

Found in New Jersey, North America.

Biseleniuret of Zinc and Proto sulphuret of Mercury. Del Rio.

a. RIOLITE, No. 55.

Q.J. 4.232. P.M. and An. 4.113.

Occurs massive, structure granular. Sp.gr. 5.56. Lustre metallic. Colour light grey.

Found at Culebras in Mexico.

Biseleniuret of Zinc and Bisulphuret of Mercury. Del Rio.

CULEBRITE, No. 56.

P.M. and An. 4.114.

Occurs massive. Fracture earthy. Sp.gr. 5.66. Dull. Colour dull red.

Found at Culebras in Mexico.

Silicate of Zinc.

a. SMITHSONITE. *Electric Calamine*, No. 168.

Haüy, 4.175. Phil. 254. Haid. 2.108. Leon. 216.

Occurs in attached, and globular, and botryoidal aggregations of crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 102° 35′. Cleavage parallel to the lateral planes. Fracture uneven. Hard. 5.0. Sp gr. 3.38. Transparent, translucent. Lustre vitreous. Colour white, brown, yellow, greenish, and bluish. Streak white.

Found at Matlock in Derbyshire, in other parts of England, and in many other parts of Europe.

Sulphate of Zinc.

a. LISTERITE, No. 539.

Haüy, 4.198. Phil. 356. Haid. 2.46. Leon. 110.

Occurs crystallized and massive.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 91° 7′. Fracture conchoidal. Hard. 2.0, 2.5. Sp gr. 2.036. Transparent, translucent. Lustre vitreous. Colour white, occasionally reddish or bluish. Streak white.

Massive varieties, botryoidal, reniform, stalactitic; structure fibrous. Amorphous, structure granular, compact. Sometimes coating other substances.

Found in most mines that contain the sulphuret, from the decomposition of which this species appears to be produced.

Sulphuret of Zinc.

BLENDE, No. 71.

Haüy, 4.186. Phil. 351. Haid. 3.32. Leon. 622.

Occurs in attached crystals and massive.

Primary form a Cube. CRYST. fig. 56. Cleavage parallel to the planes of the rhombic dodecahedron. Fracture conchoidal. Hard. 3.5, 4.0. Sp.gr. 4.07. Transparent to opaque. Lustre adamantine. Colour white, (New Jersey, North America,) black, brown, red, yellow, green. Streak paler.

Massive varieties, globular, botryoidal, reniform, stalactitic; structure fibrous. Amorphous, structure crystalline, granular, compact. A fibrous variety contains cadmium.

Found in many parts of Europe and America.

Zinc and an Acid not yet ascertained.

a. HOPEITE, No. 571.

Haid. 3.109. Leon. 746.

Occurs in attached crystals.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 101° 24′. Cleavage parallel to the great diagonal, distinct. Fracture uneven. Hard. 2.5, 3.0. Sp.gr. 2.76. Transparent, translucent. Lustre vitreous. Colour greyish-white. Streak white.

Found at Altenberg near Aix la Chapelle.

b. TEPHROITE? No. 570.

Leon. 782.

Occurs amorphous. Fracture uneven. Hard. 5.5. Sp.gr. 4.10. Lustre adamantine. Colour ash-grey, becoming black externally.

Found with Franklinite, &c. in New Jersey, North America.

ZIRCONIA.

Silicate of Zirconia.

ZIRCON. *Hyacinth. Jargoon*, No. 180.

Haüy, 2.291. Phil. 99. Haid. 2.368. Leon. 387.

Occurs in attached, imbedded, and loose crystals.

Primary form a Square prism. CRYST. fig. 65. M,c (fig. 68) = 132° 12′. Phil. Cleavage parallel to the lateral planes, indistinct. Fracture conchoidal. Hard. 7.5. Sp.gr. 4.5. Transparent to opaque. Lustre nearly adamantine. Colour grey, brown, red, yellow, pale green. Streak white.

Found in many parts of the World.

Titaniate of Zirconia, Cerium, &c.

ÆSCHYNITE, No. 397.

E.J.S. N.S. 3.28. P.M. and An. 10.188.

Occurs in imbedded columnar crystals in mica and felspar.

Primary form a Right rhombic prism. CRYST. fig. 71. M,M′ = 127°. Cleavage not apparent. Fracture uneven. Hard. 6.0, 7.0. Sp.gr. 5.14. Opaque. Lustre imperfect, metallic. Colour black. Streak greyish-black.

Found at Miask in Siberia.

ZOIZITE, No. 290.

Haid. 2.282. Leon. 476.

Occurs in imbedded and aggregated columnar crystals.

Primary form an Oblique rhombic prism. P,M (unknown.) M,M′ = 116° 30′. Fracture uneven. Translucent. Lustre vitreous. Colour white, grey, brown, green of several shades.

Found in Carinthia, the Tyrol, Siberia, and other places.

ZURLITE, No. 305.

Monticelli, Prodromo de la Mineralogia Vesuviana, p. 392. Leon. 787.

Occurs crystallized and massive.

Primary form a Cube or Square prism. Fracture uneven. Hard. 4.0, 4.5. Sp.gr. 2.274. Colour asparagus-green.

Found at Vesuvius.

INDEX.

THE names of those species which are placed in their *alphabetical* order in the preceding *List* are also repeated in this Index for the purpose of giving the entire series of species alphabetically. Those which are chemically arranged in the List will be found here, accompanied by references to the chemical groups in which they stand in the List.

Many synonymes, now nearly obsolete, are omitted in this Index, and it is much to be wished that the Mineralogists of different Countries could agree upon some single nomenclature, which might render a future repetition of any synonymes altogether unnecessary.

CHAPTER I.

PROGRESS AND PRINCIPLES OF THE SCIENCE.

Geology. Ch. I.

Progress of the Science.

THE term Science, as now universally employed, is understood to express, not only the body of information collected, general laws established, or system recognised in any department of human knowledge, but also the ultimate objects and whole scope of the research. Strictly speaking, perhaps, the former is its legitimate meaning. Thus the Science of Optics or of Acoustics properly signifies the body of methodized information acquired in those branches of human study, but is popularly understood, by way of anticipation, to include indefinitely the expected or possible future accessions of knowledge on the subject.

It is in conformity with this ordinary language that we shall endeavour to give the definition of Geology; for though truly none of the Sciences of observation has made more remarkable progress toward successful generalization than this, yet the prospect of further discovery is so much richer than the retrospect, and the activity and talent employed in the research is so much on the increase, that we can hardly offer too bold and expanded an expression for the ultimate aims of Geology.

It might provoke a smile to recount the singularly contracted notions on this subject which have till lately figured in Works on Geology. The history of the Deluge, the discussion of the character and repositories of minerals, the classification of fossils, the causes and effects of volcanos, belong indeed to this comprehensive subject, but these and many more important inquiries, are only particular branches of the great study of Geology.

One reason of the inadequacy of the definitions usually presented, is probably not confined in its application to any one of the Sciences of observation, *viz.* the difficulty of foreseeing at the commencement of a new study, the direction and extent of its future developement. Mathematical Science, founded upon the pervading idea of relative magnitude, may by this comprehensive definition, anticipate all the various determinations concerning number, and proportion, and direction, which are daily added to its stores, and which are, in fact, the developements of recognised fundamental axioms; but the Natural Sciences have not this advantage, and it is only after they have made great progress, and many detached inferences, drawn from still more scattered data, have been combined into system, that the most able cultivators can clearly discern whereto their labours eventually tend.

Definition. Guided by these views, we shall define Geology as that Science to which it is allotted to investigate the ancient Natural History of the Earth; to determine by observation what phenomena of living beings or inorganic matter were formerly occasioned on or within the Globe, in what order and under what conditions; and from comparative data, furnished by investigation of the present operations of Nature, to infer the general system of successive revolutions which the Earth has undergone before arriving at its present state; and thus, finally, to furnish a complete view of the conditions which have regulated, and of those which do regulate, its system of mechanical, chemical, and vital phenomena.

From the terms of this definition we may at once understand why, in former times, the most able men erred so grievously in their attempts to elucidate the history of our Globe; for, while Geography was imperfectly known, before Commerce and the knowledge of Languages had made us acquainted with the productions and traditions of every clime, before the birth of most branches of Physical Science, it was impossible to accumulate the numerous and exact data from which alone Geology takes its origin. And since the general truths of Geology are made apparent only by the application of the known laws of Modern Nature, it is evident that, before the establishment of those laws, the wisest of the old Philosophers had nothing to substitute for enlightened theory but blind and fanciful conjectures. These are the reasons why the ancient doctrines concerning the World are almost without exception bewildered with the impossible problem of the Creation of Matter, and buried in a chaos of subtle inventions.

Speculative Geology. Cosmogony, not Geology, is the subject of the old traditions of Phœnicia, Chaldæa, Egypt, and China; and the same incurable fault vitiates the learned systems of Epicurus, Aristotle, and Pythagoras.

It is, however, interesting to observe a considerable refinement in the nature of the fictions by which those great men attempted to supply the want of fair deductions. The Epicurean doctrine of atoms, and the primary elements of Aristotle and Pythagoras, are favourably contrasted with the Egyptian egg of the World and the primeval monsters of Chaldæa. Familiarized with Countries in which frequent earthquakes and occasional volcanic eruptions necessarily accustomed the mind to a contemplation of great revolutions in Nature, we find both Aristotle and Pythagoras indulging the ideas of frequent changes in the relative extent of land and sea, and supporting this doctrine by reference to historical facts concerning subsidence and elevation of land, to the occurrence of marine shells far from the sea, and to the ordinary processes of Nature. But, in this respect, the Geographer Strabo appears to have far outstripped all his predecessors; for he distinctly alludes to the various explanations of the phenomena of marine remains, proposed by Eratosthenes, Xanthus, and Strato, and adds his own view of the matter, in terms not very different from those employed at the present day by the advocates of the gradual elevation of our solid land from the bed of the sea, as may be known by consulting the excellent review of Geological opinions given by Mr. Lyell.

The ten centuries of war and commotion which suc-

ceeded the destruction of the Western Empire, were less favourable to the growth of Physical Science than even those which had preceded; and while all the learning of the world was shut up in cloisters, and confined to one class of Society, we cannot wonder that the grand cosmogonies of the Ancients should have dwindled into puerile discussions. Learning was in chains, but it was nevertheless spread abroad through Christendom, and waited but for the extension of Geography and Commerce, by the maritime discovery of India and America, to be emancipated from its thraldom, and for the discovery of the Art of Printing to be excited to energy and enthusiasm, by the Physical and Astronomical discoveries of Kepler and Galileo.

It was not, indeed, till the Inductive Philosophy, budding in Galileo, blossoming in Bacon, and rich with fruit in Newton, had been widely disseminated among mankind, that we were entitled to look for fixed data and limited generalizations in any branch of Natural Science. The diffusion of this mode of philosophizing may be said to have withdrawn the veil of prejudice which had previously obscured the visible Creation, and to have really generated the Sciences which treat of the properties of Matter and the phenomena of Life.

Three different classes of phenomena have conducted men of observation to a partial acquaintance with the stratification of the crust of the Earth.

Origin of Inductive Geology.

1. The arrangement of the various soils in England.
2. The appearances in the mines of Germany.
3. The remains of plants and animals entombed in the strata of England, France, and Italy.

Agriculture.

The early advancement of Agriculture in a Country so populous, and of so diversified an aspect as England, necessarily produced a very intimate knowledge of different soils; and as these depend on the nature of the substances beneath, which range in regular courses, it is not surprising that maps of the soil should have been early proposed by agriculturists. Dr. Lister, residing in Yorkshire, where the ranges of soil are very well defined, was the first to propose to the Royal Society, in 1683, a Map of the soils of England.

"We shall be better able," he says, "to judge of the formation of the Earth, when we have duly examined it, as far as human art can possibly reach, beginning from the outside downwards. And for this purpose, it were advisable that a Soil or Mineral Map, as I may call it, were devised. The soil might either be coloured by a variety of lines or etchings: but great care must be taken very exactly to note on the Map where such and such soils are bounded. As for example, in Yorkshire, the *woods*, (wolds,) chalk, flint, and pyrites, &c. 2. *Blackmoor*, moors, sandstone, &c. 3. *Holderness*, boggy turf, clay, sand, &c. 4. *Western mountains*, moors, sandstone, coal, ironstone, clay, sand, &c. *Nottinghamshire*, mostly gravel, pebble, clay, sandstone, hall-plaster, or gypsum, &c. Now if it were noted how far these extended, and the limits of each soil appeared on a Map, something more might be comprehended from the whole and from every part, than I can possibly foresee, which would make such a labour very well worth the pains. For I am of opinion such upper soils, if natural, infallibly produce such under minerals, and for the most part in such order. But I leave this to the industry of future times."

This scheme was partly executed by the County Reports presented to the Board of Agriculture, the earliest of which dates from 1794; but the investigation being usually unconnected with sound views of the interior conformation of the Earth, few of these detached efforts led to any important results. Packe, in his *Chorographical Chart of East Kent*, (1743,) has shown what admirable general views of the Physical Geography and leading rocks of a district may be entertained, without that combination of results which leads to Geology.

Mining.

Miners in every period must have been acquainted with the order of succession of the rocks through which they seek the treasures of coal and metal; and in a tract consisting of alternating coal-seams, limestones, sandstones, and shales, as at Aldstone Moor, in Cumberland, the range and extent of the different strata must always have been familiar to the workmen.

There must therefore always have been a MINERALOGICAL SCHOOL OF GEOLOGY in every Country in which rich subterranean treasures attracted the attention of mankind.

Agricola embodied the floating information of the miners of Saxony, as early as 1546; (*De Naturâ Fossilium*;) and the appearance of five complete systems of Mineralogy in Sweden, and three in Germany, between 1730 and 1762, sufficiently proves the very general interest in the subject which prevailed in these great mining districts.

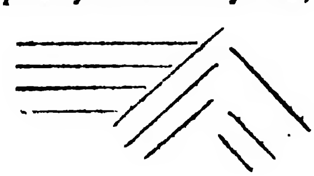
Those Works are principally devoted to a description of the most prominent Minerals, and it is only incidentally that we gain from them proofs of the considerable, though detached information which the authors really possessed concerning the manner in which minerals constitute, by their assemblage, the crust of the Earth.

In 1750, however, Tylas, a Swede, and in 1756, Lehmann, a German, broke through the fetters of a mere mineralogical method, and by proving a regular order of superposition among stratified rocks, opened the way to the sagacious generalizations of Werner and the cautious inductions of Saussure.

Werner

A peculiar set of opinions concerning the formation of the Earth, has been honoured by the title of the Wernerian Theory; and the pupils of Werner who had found proof of the truth of his practical inferences, may be readily pardoned for the determination which they have shown to uphold the hypothetical notions of their master. But if we wish to ascertain the real value of the benefits which the researches of Werner have conferred upon Geology, we must forget his Theory, and view only the data which he collected for its foundation.

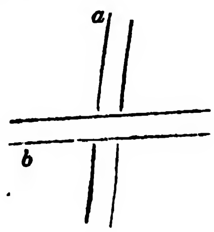
Werner was educated amidst the mines, and in the society of the most eminent Mineralogists of Saxony; their experience and their opinions became his own, and doubtless swayed and directed the energies of his mind. To judge from his own Works, and from the course which his pupils have so long pursued, the principal point of view under which Werner contemplated the rocks and metallic veins of Germany, was the relative period of their production. Lehmann had, indeed, taken the same course, and already distinguished primary and secondary rocks,



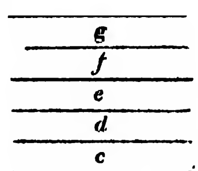
the former existing in mountain chains, mostly stratified at high angles of declination, and devoid of organic remains, the latter disposed more horizontally, and stored with the reliquiæ of life. But Werner, with characteristic tact and boldness, applied this method of investigation to every case, and took it as the grand basis of his classification of rocks.

Basis of his system.

"When two veins (a b) cross, and one of them (b) cuts through the other, (a,) the one which is divided (a) is the more ancient."



Among stratified rocks superimposed on one another, the lower members of the series, those which lie nearest the centre of the Earth, were deposited first, and the relative antiquity of the different strata is exactly in the order of their position. Thus c is the oldest rock of the series, c, d, e, f, g.



By this manner of proceeding in the instance of the Hartz Mountains, Werner was enabled to frame a system or classification of rocks in the order of their respective position as far as could then be ascertained, and consequently in the order of their consecutive formation. Thus the Brocken Mountain was described by Werner and his followers as a central cone of granite, upon which on all sides round were laid various other rocks in a certain and constant order of succession; as granite, clay-slate, limestone, greywacke and greywacke-slate, old red sandstone, limestones, gypsums, sandstones and limestones; the upper and newer strata having their outgoing or terminal edges lower and lower continually.

Werner presumed that this order of succession among these rocks would be found to prevail in all parts of the World, and thus announced a grand principle in the construction of the Earth which was destined to have a most beneficial effect on Geological theory and observation. For, on the one hand, it dissipated the chaotic dreams of those who maintained that the whole crust of the Earth was to be viewed as a mass of sediment from the waters of "the Deluge;" and on the other, exhibited the most important subject of inquiry respecting the constitution of the Earth, and fixed a precise method of investigating it.

Extending his views through other parts of Germany, Werner completed the following system of successive formations. (*Jameson.*)

Werner's series of formations.

The lowest and oldest series of rocks discoverable by examination is supposed to be of crystalline origin, to be devoid of organic remains, and to have been originally, as at present, stratified at high angles of inclination. These are called by Werner

Primitive Rocks.

Such are:

Granite,	Porphyry,
Gneiss,	Sienite,
Micaceous schistus,	Topaz rock,
Argillaceous schistus,	Quartz rock,
Primitive limestone,	Primitive flinty slaté,
Primitive trap,	Primitive gypsum,
Serpentine,	Eurite, or whitestone.

A second series of rocks appearing to be partly of crystalline and partly of mechanical origin, containing some remains of plants and animals, with slopes of stratification less remarkable than the former, is named by Werner, on account of these intermediate characters,

Transition Rocks.

Transition limestone,	Greywacke,
Transition trap,	Transition flinty slate.

The third series consists of strata more decidedly of mechanical aggregation with abundance of organic exuviæ, and from the greater frequency of these strata in the flatter regions of the Globe, where their planes of stratification are nearly level, they are called

Flœtz (flat-lying) Rocks.

1st or old red sandstone.
1st flœtz limestone.
1st flœtz gypsum.
2d variegated sandstone.
2d flœtz gypsum.
2d flœtz limestone, or muschelkalkstein.
3d sandstone, or quadersandstein.
3d limestone, or planerkalkstein.
Flœtz trap.
Independent coal formation.
Newest flœtz trap.

Lastly, various sandy and argillaceous strata, imperfectly known to Werner, but since ascertained to contain the whole vast series of tertiary strata, are included by him under the title of Alluvial Deposits.

That this classification is partly erroneous in principle, and in all respects incomplete and inadequate to the rigour of modern investigation, is apparent at a first glance, but it obviously contains the essence of all subsequent arrangements, *viz.* a determined reference to the antiquity of the deposit. Werner is, therefore, entitled to the distinguished praise of having established one of the most important general laws yet ascertained respecting the structure of the Earth. He has proved that its stratified rocks are laid one on another in a certain order of succession, which is the same, or very similar, over large parts of the Earth's surface. No one before Werner was able to perceive in any Country a regular system or series of strata, much less to imagine such a series to be universal.

Mitchell.

It has been usual, especially in England, to quote a variety of persons before the date of Werner, to whom the honour of first declaring the principles developed by the Professor of Freyberg might with more justice be ascribed. The nature of his obligations to his own Countrymen has been already sufficiently stated. Mitchell, one of the most talented of the Natural Philosophers of England during the middle of the XVIIIth Century, who, for a short time, filled the Woodwardian Chair of Geology at Cambridge, and afterwards resided in Yorkshire, had certainly made himself acquainted with the series of English strata, especially in the Northern

Counties, and had even gone so far as to discover some of the most important general relations between the Geological structure and the Physical features of the Globe, defining with a masterly hand the mutual dependence of mountain ranges and lines of stratified rocks.

Whitehurst.

The merit of Whitehurst, also, both as a theorist and as an observer, is very considerable. He states the object of his Work, published in 1792, to be "to trace appearances in Nature from causes truly existent; and to inquire after those laws by which the Creator chose to form the World; not those by which he might have formed it, had he so pleased." His mode of proceeding is exactly in conformity with the first clause of this sentence; for his whole Work is a finely woven web of plausible deduction and conjecture, founded on general Physical considerations, and *supported* or *illustrated* by a selection of corresponding facts and observations. This inverse process is certainly, in many respects, characteristic of a Cabinet Geologist; and yet this volume contains abundant proof, that its author was both well acquainted with a great variety of important data in Geology, and possessed of sufficient generalizations to develope their value. What is stated by Whitehurst concerning the succession of strata in Derbyshire and other parts, was chiefly derived from the miners and colliers, who, certainly, for a hundred years before the dawn of sound Geology, knew perfectly the almost invariable sequence of strata in their own districts.

Saussure.

The value of Saussure's distinguished services to clear the way for legitimate inductions in Geology cannot be better expressed than in the following passage of Cuvier, wherein he is compared with Werner.

En effet, la partie purement minérale du grand problême de la théorie de la Terre a été étudiée avec un soin admirable par De Saussure, et portée depuis à un développement étonnant par Werner et par les nombreux et savans élèves qu'il a formés.

Le premier de ces hommes célèbres, parcourant péniblement pendant vingt années les cantons les plus inaccessibles, attaquant en quelque sorte les Alpes par toutes leur faces, par tous leurs défilés, nous a dévoilé tout le désordre des terrains primitifs, et a tracé plus nettement la limite qui les distingue des terrains secondaires. Le second, profitant des nombreuses excavations faites dans le pays qui possède les plus anciennes mines, a fixé les lois de succession des couches; il a montré leur ancienneté respective, et poursuivi chacune d'elles dans toutes ses métamorphoses. C'est de lui, et de lui seulement, que datera la Géologie positive, en ce qui concerne la naturale minérale des couches: mais ni Werner ni De Saussure n'ont donné à la détermination des espèces organiques fossiles dans chaque genre de couche, la rigueur devenue nécessaire, depuis que les animaux connus s'élèvent à un nombre si prodigieux.

Inductive Geology principally founded on the organic reliquiæ.

The grand fact upon which, in all Ages, Geological inquiries have hinged, the occurrence of marine animals far from the sea and deep in the solid bosom of the Earth, was so far understood by the Ancients, that they had ascertained the general agreements of fossil and recent marine shells, nor does there appear the least trace of doubt on this subject in their writings. But warm discussions arose concerning them among the Naturalists of Italy, and at a later period, those of France, England, and Germany, Countries in which those exuviæ are particularly plentiful and various.

The XVIth Century was wholly wasted in the ridiculous dispute whether the fossil shells were genuine marine exuviæ, or mere *lusus naturæ* produced by a plastic power or fermenting fatty earth? and the question assumed a more difficult character from the addition of another, whether, if they were genuine petrifactions, they were all deposited by the Noachian Deluge? In examining both of these points the Italian Philosophers were by far the most conspicuous, and it is difficult to understand how the sound conclusions of Steno and Scilla could fail to become the universal creed of Geology; yet long after Palissy in France had produced unanswerable evidence that fossil shells were the genuine exuviæ of ancient marine animals, men voluntarily shut their prejudiced eyes to this most simple of all truths. The XVIth Century closed before the expiration of this absurd controversy; but as Truth infallibly gains strength by even the most unworthy contests, the strong interest attached to the solution of this problem spread universally among Naturalists the conviction that great discoveries concerning the structure of the Earth were to be accomplished, and the mode of contemplating its connection with Zoology received very capital improvements.

Progress of Fossilogy in England.

In England, especially, the superior interest which belonged to the thousands of fossil plants and animals, was fully understood by Llwyd, Ray, Lister, Woodward, and Moreton; who by their rich collections, and splendid publications, and resolute though unsuccessful efforts to deduce the causes which had thus buried and preserved imperishable in their everlasting tombs the organic remains of a former World, undoubtedly kindled that ardent spirit of inquiry respecting the structure of the Earth, for which the English Philosophers of the XVIIth Century were so honourably distinguished.

Nevertheless, the progress of Geology in England was still retarded by the fettered condition of other Sciences, and by a peculiarly unhappy conjunction of Truth and Fiction. The correct view of the original nature of "formed stones, or petrifactions," was coupled by Woodward and his numerous followers with the assertion, that all the strata superimposed on one another in the crust of the Earth, with all their included myriads of fossil animals and plants, were deposited by one general flood, "the Deluge!" This fatal error, the stumbling-block of the Geologists of the XVIIth Century, lay at the root of the brilliant hypotheses of Burnet, Woodward, and Whiston; and now, though discarded by every sound Geologist, it remains a serious impediment to the diffusion of correct general principles. One great merit, however, strikingly characterises the early English School of Geology, even in its greatest aberrations, a thorough conviction that the organic remains entombed in the Earth were the surest evidence of the revolutions which it had undergone.

Lister.

In consequence, the whole island was filled with collections of fossils, which were compared with native and exotic living species, and almost every Naturalist of note from the time of Lister contributed something to the stock of information respecting them. That distinguished man, equally industrious and fortunate, and in general free from theoretical prejudice, had the glory of perceiving and of recording in a single instance the principle of mutual dependence between the strata and their organic remains, which afterwards, generalized and promulgated by Smith, became the most important instrument of investigation which has ever been presented to Geology.

Speaking of a small species of belemnites, (*B. Lis-*

teri,) which is figured in his *Historia Animalium Angliæ*, he says it is found in all the cliffs *as you ascend the wolds*, for above a hundred miles in compass, at Speeton, Londesbro' and Caistor, but always in a *red, ferruginous earth*. This correct and remarkable result is a striking example of the possibility of even holding in the hands a brilliant discovery, without knowing its value, or taking any steps to ascertain its importance.

Smith.

A century later, the perception of the same truth, in *several instances* near Bath, and the demonstration of its applicability to the whole secondary series of the strata of England, enabled Mr. Smith, by his own unaided efforts, to establish the Geology of England on a basis from which it can never be shaken; an accurate classification of the stratified rocks, in the order of their relative antiquity, accompanied by Catalogues of their organic contents, and a Map of their ranges on the surface of the Island in conformity with the section of the interior.

The following Table, taken almost verbatim from Dr. Fitton's valuable notes on the History of English Geology, (*Phil. Mag.* 1832,) presents the list of English strata as published by Mr. Smith in 1815, and the corresponding arrangement at present admitted among Geologists; and thus at one view may be seen the entire distinctness of Mr. Smith's whole system of classification and method of naming, from that of any earlier continental writer, and the almost perfect exactness with which his views and names have been adopted by the modern School of English and European Geology.

Smith, 1815. Characters of natural Districts formed by Groups of Strata.	No.	Names of Strata on Mr. Smith's Map and Sections.	1833.		Present Names.
		(*These beds above the chalk not noticed by Smith.*)	Strata above the chalk		Crag of Suffolk. Marine and freshwater strata of the Isle of Wight and Dorsetshire.
Plains	1	London clay			London clay.
	2	Clay or brick earth			Plastic clay.
	3	Crag (*this should have been placed first*)			Sands above the chalk.
	4	Sand and light loam			
Chalk hills	5	Chalk {Upper, with flints; Lower, without flints}	Cretaceous strata		Chalk {Upper. Lower.
	6	Green sand			Upper green sand.
Clay vales	7	Blue marl			Gault.
	8	Iron sand			Lower green sand.
		(*The Wealden group not distinguished by Smith.*)		Wealden	Weald clay. Hastings sands. Purbeck limestone.
	9	Portland rock	Oolite strata	Upper oolite.	Portland oolite.
	10	Sand			Sand.
	11	Oaktree, or North-Wilts clay			Kimmeridge clay.
				Middle oolite.	Upper calcareous grit.
	12	Coral rag and pisolite			Coralline, or Oxford oolite.
	13	Sand and sandstone, or calcareous grit			Lower calcareous grit.
	14	Dark blue, or Clunch clay			Oxford clay.
	15	Kelloway stone			Kelloway stone.
Stonebrash hills	16	Cornbrash		Lower oolite.	Cornbrash.
	17	Hinton sand and sandstone			Sand and sandstone.
	18	Forest marble			Forest marble.
	19	Clay			Bradford clay.
	20	Great oolite			Great oolite.
	21	Fullers' earth and rock			Fullers' earth and rock.
	22	Under oolite			Inferior oolite.
	23	Sand			Sand and grit.
	24	Marlstone		Lias	Upper lias clay.
Marl vales	25	Blue marl			Marlstone.
					Lower lias clay.
	26	Blue lias			Blue lias.
	27	White lias			White lias.
	28	Red marl and gypsum	Saliferous strata		Red marl and gypsum.
					Red sandstone.
	29	Magnesian limestone			Magnesian limestone. (Zechstein, &c.)
Coal tract		Soft sandstone			Rothetodtelliegende.
	30	Coal districts	Carboniferous strata		Coal measures.
Mountainous	31	Mountain limestone			Mountain or carboniferous limestone.
	32	Red and dun stone			Old red sandstone.
	33	Various, killas or slate			Slates, &c.
	34	Granite, sienite, and gneiss			Granite, &c.

To study the monuments of Nature according to the principles developed by Mr. Smith; to ascertain by the order of succession and by the organic remains what were the contemporaneous effects of the natural agents employed in the formation of the Earth in all parts of the World; is the great problem of modern Geology. By the aid of Zoological and Botanical researches we determine the *relative* antiquity of every species of fossil plant and animal, and assign the *relative* period during which its existence was continued. Orthoceratites productæ, trilobites, and many crinoides, belong to the older and lower rocks; certain species of echini and shells mark the oolitic strata; while others belong to the chalk; and a series of plants, corals, shells, and vertebral remains, lies above the chalk, but is not found below. Such inferences, drawn from observations in Europe, have been found constant even in the New World; and if the powerful instrument of research thus placed in the hands of the observer, be wielded with the caution requisite in questions of analogy, the time is probably at hand when the principles disclosed by Mr. Smith's researches near Bath, and illustrated by Cuvier's philo-

sophical description of the environs of Paris, will be found universally applicable; and the distant slopes of the Himalayah and the Andes, and the shores of Australia and Greenland, will be united in the mind of the Geologist who contemplates their coeval stratification.

Hypotheses.

We shall here close our short account of the growth of Geology into a Science, without being tempted to indulge in the vain amusement of ridiculing those crude and visionary schemes which have too long been known by the misapplied title of Theories of the Earth. While the paths of observation, along which alone the foundations of the Science are to be sought, were hard and difficult, those of hypothesis were easy, flowery, and inviting. The globular figure of our Planet, the inequality of its surface, and the occurrence of marine shells in mountains far from the sea, have been thought sufficient data for rashness and speculation to construct detailed Theories of the Earth, to determine the constitution of its centre, and to describe, as if they had actually beheld them, the successive revolutions which it had undergone.

These unfortunate hypotheses were most numerous and discordant during the period when positive Geology had made the least progress; with the advancement of knowledge they diminished in number and improved in consistency, and at the present moment, though every professed Theory has lost its power of fettering the mind, there is a tacit but almost universal agreement in these fundamental principles of structure, and circumstances of origin, by which not only every passing Theory must be judged, but to which also all good observations and sound inductions must be referred. To develope these principles in a settled order, to illustrate by their aid the Geological structure of the British Isles, and to connect the Geology of Britain with that of Europe and the terraqueous Globe at large, and thus to rise by a legitimate process to the most comprehensive inferences which the subject admits of, is the aim of the following pages.

We shall not, at the outset of our inquiry, prejudge the important questions which will arise for discussion, by deciding between Huttonian and Wernerian, or any other hypotheses; but allowing to their ingenious authors the merit of having really promoted Geology by stimulating curiosity and by directing inquiry, we shall for the present neglect them altogether, except so far as they may assist us to read well and interpret aright the rich and impartial volume of Nature.

Modern cultivators of English Geology.

But though Geology will not again own a master, its cultivators can never cease to be grateful to their ancient leaders; and many names connected with the general progress of English Geology in recent times, here demand the warmest expression of gratitude. The English system of Geology, based on the extensive labours of Smith, has been fully illustrated in Greenough's *Geological Map*, Buckland's *Reliquiæ Diluvianæ*, and Conybeare's *Geology of England and Wales*, a Work certainly not yet surpassed in merit, nor soon to be excelled unless by the continuation of it, which is anxiously expected, from the combined labours of Conybeare and Sedgwick. Scotland has been surveyed by Jameson and Mc Culloch, amply described by Boué, and put in relation with English Geology by the eminent researches on secondary rocks of Sedgwick and Murchison. Nearly the whole of Ireland has been ably treated by Weaver. The mineral condition of the British Islands has been to a great extent developed by Sowerby, and the history of British fossil plants is in the hands of Lindley and Hutton. If from these comprehensive Works we should pass to those more local and definite discoveries which are the ultimate strongholds of the Science, many pages would not suffice to hold the praise so justly ascribed to De la Beche, Farey, Horner, Lonsdale, Lyell, Mantell, Miller, Webster, and other eminent names which will appear in the following descriptions. To the Geological Society of London, established in 1807, as a Body, belongs the high and enviable praise of unwearied and exciting activity, sound preference of permanent facts to transient Theories, invincible liberality of sentiment, and prophetic anticipation of that glorious expansion of the Science, which now claims for it the countenance and the active cooperation of every person interested in the interpretation of Nature, or concerned in the increase of the national wealth. Finally, there is yet a tribute to be offered to one whose ear is now dead to grateful praise, the man whose genius restored the vanished forms of Nature, and united the Zoology of all Ages of the World. What monument can be required for Cuvier, so long as the wonderful works of Creation claim the admiration of mankind?

Materials in the Earth.

Mean density of the Earth.

The first question which presents itself to the inquirer into the Natural History of the Earth is, what are the materials employed in its construction? To answer this question fully, and in all its extent, is now, and will, probably, for ever remain impossible, because with respect to the interior of the Globe we can learn nothing from direct observation, nor infer from Astronomical researches any thing more than that the materials, whatever they are which compose the more central parts, must have *there* a Specific Gravity, very much greater than that of the rocks which appear near the surface. The mean density of all the predominating rocks hitherto discovered is about twice and a half that of water; but the mean density of the whole terraqueous mass is four and a half times, or perhaps five times that of water. We may, therefore, safely conclude that the central portions are much heavier than the external crust; but beyond this all is speculation.

Specific Gravity of the materials.

It must not be concluded that because in the central parts the materials, whatever they are, have a Specific Gravity greater than those near the surface, they would also remain heavier if brought to the surface, for the compressibility of Matter under pressure would necessarily tend to the condensation of the internal nucleus of the Earth, and that in so high a degree, if the internal substances be of the same compressibility as those in the crust of the Earth, as to make the mean density of our Planet very much higher than it is known to be. Putting out of view the question of the Chemical relations of the internal substances of the Globe, and confining ourselves to Mechanical considerations alone, we should have, as conclusions of the greatest probability which the subject admits of:—

First, that the superior density of the internal parts of the Globe is occasioned by the accumulated pressure which they have to sustain.

Secondly, that the effects of this pressure in condensing the internal parts of the Globe would be far more considerable than they are, were they not resisted within by some general antagonist force; such as the

expansive power of heat, or an extraordinary want of compressibility among the particular substances operated on.

Thirdly, That the Earth's spheroidal figure has been attained in consequence of its having formerly been entirely fluid, during rotation on its axis, and is preserved because the internal arrangement of its materials, whether solid or fluid, is in equilibrio with the velocity of its rotatory movement.

Limitation of inquiry.

It cannot be too often nor too early impressed upon the mind of the student that Geology has no connexion with systems of Cosmogony. It is wholly a Science of observation and inferences, and limited to the phenomena presented within a small depth from the surface of the Earth. The regular disposition of the materials of our Planet does indeed permit us, in many cases, to infer, with the highest probability, what is the condition of its interior to a depth far beyond that actually visible to human eye; but still all the aids of Inductive Science are ineffectual to penetrate more than a few miles below the soil. It may, indeed, be the case, since the level from which volcanos arise is uncertain, that the materials which they vomit have been derived from greater depths, but the great improbability that these materials, after undergoing fusion, should be restored to their original condition, must make us hesitate to adopt volcanic products as evidence of the exact nature of the substances in the interior of the Earth. Our observations are, therefore, nearly confined to what is technically called the Crust of the Earth, and our legitimate inferences descend no lower than the rocks which appear in this crust.

Earthy compounds

There is hardly any tract of country so limited as not to show a considerable diversity of earthy aggregates. Even in those districts which possess neither quarries, nor mines, nor cliffs, nor natural valleys, the surface of the land and the shores of the sea are generally strewed with fragments of different stones transported by some ancient powerful currents from regions in which Nature is more prolific, or more clearly reveals her treasures.

In the more level Countries the principal varieties of the earthy compounds or aggregates are included in the terms limestone, sandstone, and clay, of different colours, hardness, and fineness of grain. Each of these great divisions of rocks contains essentially a peculiar species of earth which imparts to the mass a particular derivative character. Thus,

Lime is the base of limestone,
Silica of sandstone,
Alumine of clays.
Magnesia is an essential ingredient in certain *limestones*.
Carbon is the characteristic element of coal,
Soda of salt.

If we now turn our attention to the mountainous tracts, where crystallized minerals present themselves in an endless variety of combination; we shall, perhaps, be led to expect a corresponding abundance of primitive substances. But Chemistry has taught us that all this seeming inexhaustible variety is occasioned by a few earths, metals, and combustibles, and some of these are so rare, and even solitary in their occurrence, as to be of little importance in this inquiry. By far the greater number of earthy minerals are composed of the same four substances, as limestones, sandstones, and clays, variously combined with alkalies and acids, and differently coloured by metallic oxides, &c. A good general knowledge of silicious, aluminous, calcareous, and magnesian minerals and rocks, is therefore the portion of Mineralogy most essential to a Geologist.

Elementary substances.

All the various aerial, liquid, and solid compounds which belong to this Globe are reducible to about fifty-four ingredients, which are termed simple or primitive, because, in the present state of Chemical Science, they appear incapable of further decomposition. Of these

Forty-three are *metallic bodies*, brilliant, electropositive, and, with the exception of potassium and sodium, heavier than water.

Of these thirteen produce, by union with oxygen, the Earth and alkalies,—

Aluminum, Silicium, Yttrium,
Glucinium, Thorinium, Calcium,
Magnesium, Zirconium, Strontium,
Barium, Lithium, Sodium, Potassium.

Five decompose water at a red heat,—

Manganese, Zinc, Iron, Tin, Cadmium.

Twenty-four do not decompose water at any heat. The more oxidable are,

Arsenic, Antimony, Copper,
Molybdena, Uranium, Tellurium,
Chrome, Cerium, Nickel,
Vanadium, Cobalt, Lead,
Tungsten, Titanium, Mercury,
Columbium, Bismuth, Osmium.

The less oxidable,—

Silver, Rhodium, Gold,
Palladium, Platinum, Iridium.

Eight non-metallic combustibles,—

Sulphur, Iodine, Carbon,
Phosphorus, Bromines, Fluorine?
Silenium, Boron.

Four gases,—

Hydrogen, Oxygen, Azote, Chlorine.

Every substance in this list is found in the mineral kingdom; and while the Chemist examines them separately in his closet, the Mineralogist studies their combinations in the field.

Minerals.

It may, perhaps, be imagined that innumerable combinations are derived from these fifty-four primary ingredients. But as many of them are excessively rare, as the remainder combine only upon certain principles, the number of mineral species really determined is, in fact, very small, perhaps hardly exceeding 300. Nor is the Geologist always called upon to make himself acquainted with all even of this moderate number. Unless his labours are devoted to the detailed phenomena of volcanic productions, or of mineral veins, he will seldom have occasion to observe more than one-tenth of the number. The reason of this is that a large portion consists of rare and local species, and that in combining to form rocks, the others are associated in families, and united into specific compounds without much permutation. Thus quartz, felspar, hornblende, chlorite, and mica, frequently occur together in granitic rocks, but other minerals, as calcareous spar, &c. scarcely ever accompany them. In consequence, then, of the rarity of many minerals, and the uniformity of the assemblage of others, there is really much less difficulty than might be expected in recognising and discriminating the rocks. To class and to describe them is difficult, to compare and to know them is easy.

Supposing, then, that the student has already made himself acquainted with the more common and remarkable rocks, as limestone, sandstone, and clay, various kinds of slates, basaltic, porphyritic, and granitic rocks,

we shall now proceed to inquire in what manner they are arranged in the Earth.

Stratification.

The best way of prosecuting this inquiry, is to begin at home, where precise information can be most easily acquired; next to compare our own with neighbouring districts; and, finally, extending our views over the whole surface of the Globe, to class the phenomena, and deduce the general results.

Arrangement of rocks on the surface.

It might be very excusable before Countries were cleared and cultivated, and before their various mineral productions were employed and understood, to imagine that the materials of the Earth were heaped together in confusion, the result of a chaotic formation; but at present, such a notion will not stand the test of a moment's reflection. One district has chalk beneath the surface, another limestone, a third coal, and a fourth granite, and these are never mixed or confounded together; so that the most careless observer must conclude that the different rocks are arranged after some ascertainable method. These different rocks are not mere insulated patches irregularly scattered through the country, but generally connected on the surface in long ranges, which in all the Eastern half of England have their prevailing direction from North-East to South-West. Thus the chalk of the Yorkshire Wolds is prolonged (see the Map of the British Isles) through Lincolnshire, Norfolk, Suffolk, Bedfordshire, Wiltshire, Dorsetshire, &c; the oolitic limestones range through Lincolnshire, Northamptonshire, Gloucestershire, and Somersetshire; and many other limestones and sandstones hold a parallel direction. Hence it happens, in proceeding from London toward the South-West, West, or North-West of England, we cross so great a variety of rocks, and so many ranges of hills.

A person proceeds from London to North-Wales. After passing low, gravelly plains in the drainage of the Thames, he climbs, by a long slope, the chalk-hills of Oxfordshire; crosses vales of clay and sandstone; ascends a range of oolitic limestone; traverses wide plains of blue and red marl; arrives in districts where coal, iron, and limestone abound; and, finally, sees Snowdon composed of slate. And if, in proceeding from London to the Cumberland Lakes, he finds the same succession of gravelly plains, chalk hills, clay vales, oolitic limestone ranges, blue and red clays, coal, iron, and limestone tracts, succeeded by the slate rocks, which compose the well-known summit of Skiddaw, will he not conclude that something beyond mere chance has brought together these rocks in such admirable harmony? Will he not have reason to conjecture that in the *interior* of the Earth regularity of structure must prevail?

Internal arrangement of rocks.

This conjecture becomes certainty when we explore the relative position of rocks as it is displayed in wells, pits, quarries, and mines, the works of human industry, or laid bare in cliffs and ravines by the hand of Nature. Here we see the rocks formed in layers or tabular masses of various thickness, but always of very great superficial breadth or extent and placed upon one another like the leaves of a book. These layers are called strata. Along the edges of hills, in the course of precipitous valleys, and by the margin of the sea, it not only is not difficult to recognise this truth, but it is almost impossible to avoid perceiving it.

Many parts of the English coast present what is termed a natural section of the rocks, and accordingly whoever visits the shores of Northumberland, Yorkshire, Kent, Hampshire, Cornwall, South-Wales, or Cumberland, may easily satisfy himself of the stratification of most of the limestones, sandstones, clays, and slates of England. For most of the cliffs are composed of several distinct layers of rock, which are piled one upon another in a regular order, preserve a definite thickness, and appear under the same circumstances in many distant places. In the interior of the country the same conclusion is to be drawn from examining precipitous hills and deep valleys; and even in the flattest country, Art supplies the means of investigation which Nature has denied. The wells, and pits, and mines, which have been found necessary for the comfort of civilized Man, all display the same general truth, and lead us to conclude that the principle of stratification among rocks is confined to no particular Country; but whether in the New or the Old World, in Continents or in Islands, it is so remarkable and so constant, that colliers sink deep pits, and miners undertake extensive levels, in full confidence that no exception to its generality will affect the result of their enterprises. It is not a speculative truth, but a practical law of Nature, and is probably the fact of most extensive influence in the whole Theory of Geology.

So many important facts respecting stratified rocks flow in together upon the observing mind, that it is not easy to analyze them in the exact order of their occurrence. A person attentive to the subject cannot fail to discover, even in a very limited district, that the different strata which appear above one another, like the leaves of a book, are also, like them, arranged in a certain constant order of succession. A stratum which in any one situation is found beneath another will never, in any other situation, be found above it.

Superposition of strata.

As a bookbinder sometimes neglects to bind in a particular leaf, so Nature sometimes omits a particular rock; but she never misplaces the rocks, as the careless workman sometimes misplaces his pages. Let us take, as an example, the cliffs on the coast of Yorkshire, between Flamborough Head and Robinhood's Bay. Gristhorp Cliffs are crowned by calcareous sandstone rocks, which rest on a thick, bluish, argillaceous bed; under this is a brown, ferruginous sandstone, and, still lower, a thin, calcareous layer full of fossil shells. In Scarborough Castle Hill, the same calcareous sandstone, argillaceous bed, brown ferruginous rock, and fossil bed, occur in the very same order of succession. Or let us station ourselves at Leeds, and examine the coal-pits of the neighbourhood, notice how many seams of coal are cut through, and what beds of sandstone and shale, and what layers of ironstone are met with. Then, inquiring of the workmen, we shall learn that the same "set of beds" is wrought at another pit. At this other pit we shall find the same beds of coal in the same order of succession, at nearly the same distances from one another, and of nearly the same qualities and thicknesses; and this strict analogy will be found at several pits over a considerable extent of ground, and, therefore, here, as well as on the coast, we obtain proof that in a limited district the *strata are arranged with respect to one another in a certain constant order of succession.*

Declination of strata.

Pursuing our investigation, we find that the strata are generally so disposed that their planes or broad surfaces are not exactly level or parallel to the Earth's spherical surface, but sloping in some one direction, so as, in that direction, to sink deeper and still deeper

Geology. Ch. I.

into the Earth, and to be covered by other strata. This slope, this deviation from the horizontal position, is called the dip or declination of the strata; and the rocks are accordingly *said to dip or decline* to this or that part of the horizon. The different rocks which compose the interior to a considerable depth are, therefore, in consequence of this declination, exhibited in succession on the surface, and hence it is that mankind is furnished with a vast variety of mineral productions suitable to its numerous necessities.

Continuity of strata.

Any one thus far initiated in Geology, and possessed of common powers of observation, will be able to compose a list or scale of the strata which occur in his own neighbourhood, *naming them* in the exact *order of their succession or superposition*, and thus will be furnished with the means of comparing his own district with others near and distant. The results of this comparison are very important, for we thus learn that one general order of succession is observed among all the stratified rocks of England. Certain strata are locally deficient, but all those which do occur together are found invariably in the same relative position. The series of stratified rocks in the North of England, taken in a general way, is expressed by the following names: chalk, gault, Kimmeridge clay, coralline oolite and calcareous grit, Oxford clay and Hackness rock, cornbrash and Bath oolite rocks, lias shales, red marl and sandstone, magnesian limestone, coal system, mountain limestone, slate. The series in the Southern parts of England is precisely accordant, except that the magnesian limestone is there nearly deficient, and that the Kimmeridge clay is covered by some strata which do not pass the river Humber. Besides, we find the strata of the North of England actually connected by mutual extension with those of the same names in the South of England, so that we thus prove their *continuity over large tracts*, as well as the constancy of the order of their succession.

By means of these comparative observations, begun by Mr. Smith in 1790, and continued with unabated zeal by his numerous disciples, the whole series of English stratified rocks has been ascertained, and arranged in tabular order; and the Geologists of England have, in consequence, furnished to the rest of the world a standard of comparison, by which to determine how far the laws of stratification disclosed in this Island are applicable to other Countries.

Stratification a general principle.

Considerable labours remain to be accomplished before even the stratified rocks of Europe can be completely compared with those of England, and the want of evidence is still more severely felt with respect to the three other quarters of the Globe. Nevertheless, the following important general results may be regarded as certain. The *principle of stratification* is found to be *universal;* that is to say, in every Country of sufficient extent, various rocks are found to be superimposed on one another in a certain settled order of succession, and these rocks are not found only in insulated patches, but often hold their course across Provinces and Kingdoms.

Throughout the whole area of Europe, from the Oural mountains to the Atlantic, and from Lapland to the Mediterranean, the stratified masses of the Earth, taken in their generalities, are arranged upon the same principles, follow one another in the same exact order of succession, and, in fact, form parts of one vast system of rocks, once more perfectly connected than at present.

What is known of the Geology of North Africa Egypt, Syria, the Countries bordering on the Caspian, Siberia, and Hindûstan, leads to a confident belief that the same general system, modified by local circumstances, will be found applicable to the greater portion of the surface of the Old Continent.

Analogy of distant deposits.

Important agreements between the strata of North America and New Holland and those of Europe, have been already determined, and the time will probably at last arrive, when, if it cannot be proved, as Werner perhaps imagined, that similar rocks were at the same time deposited in every part of the bed of the ancient sea, at least it will be possible to show that the same system of natural processes was every where in progress, contemporaneously or successively producing analogous effects; and to ascertain the relative antiquity and accompanying circumstances of even the most distant deposits; and thus to exhibit, in chronological order, a history of all the varied yet harmonious operations, by which, in regular gradation, this Globe was filled with long-enduring monuments of the everlasting power and wisdom of its Creator, and made fit to be inhabited by a Being capable of interpreting the conditional effects, recognising the appointed agency, and venerating the universal Cause.

Distinction of Stratified and Unstratified Rocks.

Relative situation.

Stratification is, therefore, the most general condition, or mode of arrangement of the rocks which appear in the crust of the Earth; and in the wide plains and gently undulated portions of the surface, it is often the only one discoverable. A person of good discernment, who should pass his whole life in investigating the South-Eastern part of England, or the Northern part of France, might conclude, from every observation he could there make, that the external materials of the Earth were *universally* stratified.

On the other hand, the inhabitant of the mountains sees so many examples of granitic rocks, totally devoid of any appearance of stratification, and sometimes finds that structure in the slate rocks so dubious and inconclusive, that he is wholly unable to comprehend the magnificent chain of inductions derived from the study of stratified rocks. Unstratified rocks generally abound along mountain chains and groups, and very often form their axis or nucleus. Stratified rocks fill the plains, and form the encircling flanks of the mountains. When a vast mass of unstratified rock, as granite, forms the nucleus of a mountain group, the stratified materials which surround it, generally slope away on all sides, as if the granite had been protruded from below these strata, and, during the act of its uplifting, had broken them, and caused them to assume their several inclinations. Other unstratified rocks, as basalt and porphyry, appear amongst the stratified rocks, sometimes in irregularly lenticular masses, as if they had been spread in a melted state around a common centre, sometimes filling long vertical fissures in the strata, as if they had been injected from below.

Mineral characters.

On comparing together the stratified and unstratified rocks, we find their mineralogical composition extremely different. The *stratified rocks* are earthy aggregates, as sandstones, clays, or simple Chemical precipitates, as limestone; such materials, in fact, as we know to be accumulated in the same mode of arrangement by modern waters.

The *unstratified rocks*, on the other hand, are gene-

rally and evidently crystallized masses, often analogous to volcanic products, or compounds containing essentially minerals which are not known to be producible from water, but in several instances are obtainable by artificial heat, or generated in the deep furnaces of which volcanic mountains are the vents.

Stratified rocks have evidently been deposited successively from above; the lowest first, the uppermost last, in obedience to the laws of Gravity.

Unstratified rocks, on the other hand, seem to be derived from the depths of the Earth, and to have been ejected or uplifted from below the strata, as volcanic matter is protruded at the present day.

Contents.

Stratified rocks contain very generally the remains of the plants and animals which were in existence at the period of their formation, exactly as remains of the present races of plants and animals are found buried in the modern deposits of water.

But unstratified rocks contain no such evidences of watery origin or mechanical aggregation.

Origin.

By all these characters, separately and comparatively considered, the two great divisions of materials which compose the external parts of our Globe, are proved to have been produced by entirely opposite causes. STRATIFIED ROCKS are analogous to the modern PRODUCTS OF WATER, and are therefore called Neptunian, while UNSTRATIFIED ROCKS are analogous to the MODERN PRODUCTS OF SUBTERRANEOUS FIRE, and receive the names of Plutonic and Volcanic, according to the degree and circumstances of this analogy

Mode of study.

The distinction now insisted upon, between the Neptunian and Plutonic formations, between stratified and crystallized rocks, is of the highest importance, and deserves the first notice, even on the very opening of the subject of Geology. For not only are these different classes of rocks distinguished by most important general characters, but even the methods by which they are to be investigated, and the preliminary knowledge required for this purpose are entirely distinct. Amongst the stratified rocks a knowledge of Zoology and Botany is required to develope the past history of innumerable remains of plants and animals, which were buried at successive periods; on the contrary, among the mountains associated with granite, where minerals of every hue and form appear in every different combination, scientific Mineralogy is of much higher importance.

In consequence, Geology divides itself into two branches, one of which links itself with the Natural History of modern plants and animals; and the other with Chemistry and Mathematics. And we have now, and have always had two distinct groups of Geologists, whose progress and discoveries have been as different as the preliminary knowledge which their different spheres of research required.

A Geologist of adequate attainments must indeed be supposed acquainted, at least generally, with both branches of this magnificent subject, and therefore a person entirely ignorant either of Mineralogy, on the one hand, or of Zoology and Botany on the other, must be considered as only half-educated. He may, indeed, be a very useful local observer, but he must be further instructed in his Science before he can be sent to explore an unknown region, or permitted to give an opinion on the whole Theory of Geology.

As much knowledge, therefore, as can be easily gained of the minerals which enter most frequently into the composition of rocks and veins, and of the Natural History of the plants and animals whose remains lie buried in the strata, is absolutely necessary to every professed Geologist. Yet on this account the student ought by no means to be discouraged; for this preliminary knowledge will be quickly, though insensibly, acquired by an intelligent observer, in exact proportion to his need of it. In a level country composed of limestone, sandstone, and clay, the multitudes of organic remains which continually meet his eye will infallibly procure him the power of discriminating their specific forms; and among the mountains associated with crystalline granite, the endless repetition of the objects will generate a Mineralogical tact in the eye, and a Mechanical if not Mathematical notion of the structure of crystals.

The summary observations which will be introduced in this Treatise on the preliminary Sciences of Zoology, Botany, and Mineralogy, will be placed with those divisions of the subject to which they respectively belong, and where they will be the most intelligible as well as the most useful.

On Stratification in general.

Strata, the term defined.

Strata, layers, and beds, are synonymous terms. "Strata," says Professor Playfair, "can only be formed by seams which are parallel throughout the entire mass." This definition, founded upon the supposition that loose materials deposited under water must be arranged in layers parallel to the surface of the water, undoubtedly contains the general or fundamental idea of stratification, but is often too abstract for practice. The most remarkably regular and parallel seams or divisions between the strata happen in calcareous and argillaceous rocks; but the partings in sandstone are much less uniform. A particular shelly bed of stone lies at the top of the coralline oolite of Yorkshire, and may be traced for a great distance; a red band, long since noticed by Lister, lies at the base of the chalk of Yorkshire and Lincolnshire for sixty miles in compass; the cornbrash limestone, seldom more than ten feet in thickness, is continuous from Dorsetshire nearly to the Humber. In these instances, therefore, Playfair's definition applies very well; on the contrary, the beds of sandstone with coal which are interposed in the oolitic system of Yorkshire, are altogether 500 feet thick near Robin Hood's Bay, but dwindle toward the South, and are entirely deficient before reaching the Derwent.

Such beds are therefore wedge-shaped  and cases sometimes occur where, by attenuation in all directions from the centre, they become lenticular. See pl. i. fig. 1. for these and other appearances.

Interposed strata.

The strata, therefore, are not all coextensive. Limestones are probably the most persistent and regular, sandstones the most limited and local. *Local* or *interposed beds* cause the principal differences between distant portions of the same formation.

The lias of England rests immediately upon red and bluish marly clays with white gypsum: at Luxemburg, they are separated by a thick sandstone. In the North of England, magnesian limestone separates the coal from the upper red sandstone, but in other parts of the Island these two formations are in contact. In the breast of Ingleborough, the limestone beds are aggregated into one vast mural precipice or scar; but as we proceed Northwards this mass opens to admit layers of sandstone, shale, and coal, which gradually increase under Crossfell, and swell out to a vast thickness in Northumberland, so as to contain several valuable seams

of coal, thick rocks of sandstone, and abundance of shale, between the horizontally separated beds of limestone.

The oolitic strata near Bath are composed of two portions, the upper or great oolite and the lower oolite, and between them is a series of calcareous and argillaceous beds called fullers' earth beds, sometimes 150 feet thick. As we proceed Northward into Lincolnshire, the fullers' earth beds are excluded from the series; still further North the whole series is changed; so that in Yorkshire it includes thick layers of sandstone, shale, and coal. On a first view the districts of Bath and Yorkshire are very unlike, but the contemporaneity of their disposition is certain from the continuation of the same oolitic beds through both of them.

Thickness.

The *thickness* of the Beds or strata varies exceedingly and seems to have reference to the rapidity, regularity, and continuity of the deposition and the rate of drying or consolidation of the materials.

The chalk rock is about 500 feet thick, and in all this great mass we can scarcely trace any decided beds; though the layers of flint at equal distances, (four to eight feet,) and the difference of the organic remains at different depths, evidently prove a succession of stratified deposits.

The great oolite near Bath is on the contrary divided into *a certain number* of beds, definite in quality, thickness, and order of position.

Laminæ.

A certain stratified rock, therefore, is composed of one or more layers or strata, but this is by no means the last term of the analysis. Each bed is often composed of many laminæ which are sometimes parallel to the plane of the bed itself, and sometimes lie in it at different angles. Thus micaceous laminated sandstones, and in particular the best flagstones of the coal districts, are composed of a multitude of thin layers parallel to the plane of the bed, and entirely covered by plates of mica which probably cause the splitting of the stone. This appearance is very analogous to the laminated sand quietly left by the successive floods of a river.

But the coarser flagstones of the same coal districts are often composed of laminæ, laid at various angles to the plane of the bed, and in consequence producing a rough, uneven, shattery surface, and a tendency to oblique fractures; thus, in pl. i. fig. 2. *a* represents the regular, and *b* the coarse, irregular flagstones.

Such appearances of oblique lamination are occasionally found in the modern sediment of agitated waters, both in the banks of rivers and on the sea-shore.

When these oblique laminæ extend through thick beds, they sometimes cause a slight difficulty in determining the dip of the strata, and are then called *false bedding*. Some of the coarse upper beds of the great oolite of Bath, Gloucestershire, Northamptonshire, and Lincolnshire, as well as of Normandy, are remarkable for this false bedding.

But it is in the coarse sandstones that we see the most remarkable examples of this structure, as on the Scarborough coast and under Nottingham castle.

The more violent the action of water, the less regular is the internal constitution of the layers found beneath it. Let any one with this view compare the effects of the tide beating upon the sand and pebbles of the Eastern coast, or the tumultuous products of a mountain river, with the tranquil deposit and sediment on the alluvial lands near Lynn and near Hull. In the former case, the materials are frequently found heaped together in laminæ, variously and confusedly inclined to one another; in the latter they are all parallel to the horizon, and to the general plane of the surface. The former case is exactly analogous to the false-bedding mentioned in a preceding section, so general in our sandstone conglomerates, and in shelly beds of oolite; the latter is exactly like the regular lamination of clays and shales. Like effects flow from like causes, and thus we are enabled to frame very plausible conjectures concerning the condition of the waters under which the several strata were accumulated.

General terms.

In the same way as a number of similar laminæ are sometimes united into one bed of stone, so several similar beds of stone, are sometimes associated into one rock, to which a specific name is applied, as the Oolite, the Lias Limestone, &c.

Sometimes several of these rocks are grouped under the title formation, as the Bath Oolite Formation. Thus in the lias limestone-beds, the lower lias clay, marlstone-beds, and upper lias clay, as represented in pl. i. fig. 3. are all included in the Lias Formation, which rests upon the Red Sandstone Formation, and is covered by the Bath Oolite Formations.

Series of British strata.

The following Table exhibits a complete view of the whole series of British strata, grouped according to their relative antiquity into three leading divisions, the Primary, Secondary, and Tertiary strata; it being understood that such divisions are chiefly adopted for convenience, as expressing with considerable accuracy certain general analogies of origin, composition, and organic contents, which prevail amongst the members of each division, but yet are not to be considered as exclusively belonging to them.

Two of these divisions are again subdivided upon exactly the same principles into systems of strata, which are marked by certain recurrent rocks, striking analogies of composition, organic reliquiæ of similar types, and positions derived from convulsions of the same epoch.

The systems are again usefully divided into formations; these into their several component rocks; whose ultimate analysis gives the strata, beds, and laminæ of composition. The superficial accumulations of gravel, sand, peat, &c., which are classed under the head of diluvial and alluvial deposits, are not included in this list of strata.

For the sake of the student to whom the mode of considering the sequence of rocks may not be familiar, the strata are here placed in the same order as they would be found on proceeding from the surface downward. This Table should be compared with that of Mr. Smith, p. 533, and of Werner, p. 531.

Tertiary Series of Strata,

partly lacustrine, but principally marine, sandy, and argillaceous, and with some calcareous deposits, abounding in shells and other organic exuviæ, closely analogous to existing species.

Formations.	Usual thickness of Formation. Feet.		Stratified Groups.
1. Upper marine formation	50		Sandy crag with shells. Zoophytic limestone.
2. Marinolacustrine	100		Upper freshwater limestone and marls. Intermediate marine bed. Lower freshwater limestone and marls.
3. Lower marine formation	1000 or more.	London clay group.	Bagshot sand. London clay.
		Plastic clay group.	Plastic clay, with coloured sands and lignites. Shelly blue clays and sands. Pebbly green sands.

Secondary Series of Strata,

principally of marine origin, with rare and local estuary deposits; consisting of repeated alternations of limestone, flint, sandstone, sand, clay, iron ores, coals, salt, &c., with organic remains generally very distinct from existing forms of animals and plants.

Cretaceous System.

Formation.	Thickness. Feet.	Stratified Groups.
4. Chalk	600	Upper soft chalk with flints.
		Middle harder chalk.
		Lower marly chalk.
		Red chalk.
5. Green sand	500	Green and grey sands.
		Gault clay.
		Iron sand or lower green sand.

Oolitic System.

Formation.	Thickness. Feet.		Stratified Groups.
6. Wealden			Weald clay and Sussex marble.
			Hastings' sands and limestones.
			Purbeck limestones and clays.
7. Upper oolite	400		Portland oolite and other limestones.
			Kimmeridge clay.
8. Middle oolite		Coralline oolite group.	Upper calcareous grit.
			Coralline oolite.
			Lower calcareous grit.
		Oxford clay group.	Oxford clay.
			Kelloway calcareous grit rock.
			Clay.
9. Lower oolite			Cornbrash limestone.
			Forest marble and sands.
			Great oolite.
			Fullers' earth, rock, and clays.
			Inferior oolite.
			Ferruginous sand.
10. Lias			Upper lias clay, or shale.
			Marlstone beds, sandy and calcareous.
			Lower lias clay, or shale.
			Lias limestone.
			Dark marls.

Saliferous System.

Formation.	Stratified Groups.
11. Variegated sandstone. (*Pœcilite, Conybeare.*)	Variegated marls, gypsum, and salt.
	Red and white sandstone.
	Red sandstone conglomerate.
12. Magnesian limestone	Red and white marls.
	Laminated limestone.
	Gypseous red and white marls.
	Magnesian limestone.
	Marl slate.
	Rothetodteliegende.

Carboniferous System.

Formation.	Stratified Groups.
13. Coal	Alternating.
	Sandstones.
	Shales.
	Coals.
	Ironstones, &c. resting on
	Millstone grit.
14. Mountain limestone	Alternating.
	Limestones.
	Shales.
	Gritstones.
	Seams of coal.
15. Old red sandstone	Conglomerates.
	Flagstones.
	Red and white marls.

Primary Strata,

containing organic remains, mostly of extinct tribes, and only in the upper part of the series.

Slate system, including many great divisions which eventually may be classed in formations, according to their organic remains and bands of limestone. It is *usual*, but vague classification, to distinguish this system into upper or fossiliferous, and lower, or non-fossiliferous slates and limestones.

Gneiss and mica schist system, including mica schist, chlorite schist, hornblende schist, quartz rock, primary limestone, gneiss, &c.

Granitic rocks, which are not stratified, usually form the basis of the strata, and are frequently but not by any means universally followed by the gneiss and mica slate system.

Disturbed Stratification.

Strata originally level.

All strata, says Cuvier, in his admirable "Discourse on the Revolutions of the Globe," must necessarily have been formed horizontal; and this opinion, founded upon the admission that rocks composed of regular layers, containing rounded pebbles, and organic remains of watery animals, can only have been formed under water, is supported by observation. For not only do we see at the present day the deposits of water arranged in planes nearly or exactly horizontal, but we also find the ancient strata of the Earth, where undisturbed by convulsions, very nearly level. In consequence of these disturbances the strata are seldom found to be perfectly horizontal, but are often inclined at high angles, and in a few instances stand directly vertical. Their planes are generally continuous over large spaces, but they are sometimes broken and dislocated by *faults or dykes*. It is now generally admitted that the usual horizontal disposition of the strata is derived from the action of the supernatant waters which accumulated them; and that the irregular declinations and fractures which we sometimes behold, are the effects of subterranean convulsions, chiefly occasioned by internal expansion. The truth of these opinions will appear from a few plain considerations.

Subsequently disturbed.

Earthy matter deposited from water by tranquil subsidence, as clay and limestone, or accumulated during periods of moderate agitation, as sand and sandstone, must in general be accumulated into layers or strata, proportioned to the intervals of deposition; and these layers, in consequence of the fluctuation of the water and the influence of gravitation, will especially tend to be horizontal. Nevertheless they must, in a considerable degree, accommodate themselves to the surface on which they are deposited. If the bottom be level, so will be the deposit; if sloping, the deposit will be inclined; but if there be a perpendicular subaqueous cliff, no deposit can fall upon its face, nor any transported materials be accumulated parallel to it. An originally perpendicular layer or deposit of earthy materials is obviously impossible. Whenever, therefore, we behold vertical strata, we may be quite sure that they were not deposited in that form, but have been displaced by some internal movements of the Earth. Abundance of instances of this remarkable position of strata may be quoted in almost any part of the World. The Isle of Wight gives us a magnificent series of strata 1100 feet in thickness, reared into an absolutely vertical position; and this effect is the more remarkable, because the materials uplifted consist of many strata of loose sands and pebbles which most certainly have been deposited level. In the Western borders of Yorkshire, vertical strata of limestone range for miles parallel to the edge of the Pennine chain, and turn Eastward through Craven, below Ingleborough and Penygant to Settle. Magnificent examples of vertical strata are familiar to those who have visited the cliffs of Savoy, or who have perused the graphic descriptions of Saussure.

Vertical strata.

Contorted strata.

There are some remarkable instances of contorted stratification very difficult to be explained without supposing the strata to have been soft at the time of the flexure. Not to dwell on inferior examples, we shall quote the magnificent phenomena of this kind which are seen in the valleys of Chamouni and Lauterbrun, and along the shores of the Lake of Lucerne, near Fluellen. The stratified limestones of these localities are bent into such extraordinary retroflexions, as to imply repeated operations of the most violent Mechanical agency, in different directions; and observations along the range of the Alps prove that the whole of this chain has been the theatre of enormous and reiterated concussions. (pl. i. fig. 4.)

Faults.

But the most remarkable case of disturbance is when strata, either horizontal or inclined, are broken, so that on one side of the line of fracture the rocks are much higher than on the other. This difference of level sometimes amounts to 100 or even 200 yards. The succession of strata is on each side the same, their thickness and qualities are the same, and it seems impossible to doubt that they were once connected in continuous planes and have been forcibly and violently broken asunder.

The plane of separation between the elevated and depressed portions of the strata is sometimes vertical, but generally sloping a little. In this case a peculiar general relation is observed between the inclination of this plane and the effect of the dislocation. In the diagram, (pl. i. fig. 5.) for instance, the plane of separation, $z\,z$, slopes *under the depressed*, and *over the elevated* portions of the disrupted strata, making the alternate outer angles $z\,z\,b$, $z'\,z'\,b'$ *acute*. In more than a hundred examples of such dislocations which have come under the notice of the writer of this Essay, he never found an exception to this rule. A similar law is found to prevail very generally in the crossing of nearly vertical mineral veins; for instance, (pl. i, fig. 6.) $a\,a$ are two portions of a metallic vein dislocated by another vein, $b\,b$. In this case the relation of the line $b\,b$ to the lines $a\,a$, is the same as that of $z\,z$ to the lines $a\,a$, $b\,b$, $c\,c$, &c. The contrary appearances, had they occurred, would have been as represented below; and such occur in the mining district of Cornwall together with many other singular phenomena, apparently referable to subterranean disturbance, perhaps complicated with other causes, but which are with difficulty reducible to any simple mode of explanation.

The line of dislocation is generally distinguished by a fissure, which is filled by fragments of the neighbouring rocks, or by basalt, and is then called a *dyke*; or by various sparry and metallic minerals, and is then called a *mineral vein*.

Relative age of the dislocation.

The irregular operations by which these disturbances and dislocations were occasioned, seem to have happened at various periods during the formation of the strata. We know, for instance, examples of horizontal strata, as $a\,b$ (pl. i. fig. 7.) resting upon highly inclined strata, $x\,y\,z$, which must have been forced into their unnatural position before the deposit of the level strata upon them.

Such a case occurs in Somersetshire, where the coal measures lie at a steep slope beneath horizontal beds of red marl. These coal measures are also greatly broken by *faults* which in some cases *throw* or elevate the beds on one side more than seventy fathoms above those on the other side. But the beds of red marl above are altogether uninfluenced either by the steepness of the dip or the abruptness of the dislocations. Therefore the convulsions by which these effects were occasioned, happened after the deposit of the coal seams, and before the deposit of the red marl.

At Aberford in Yorkshire, and at many other points along the line of the magnesian limestone between Nottingham and Sunderland, similar examples occur.

In such cases the discordance of inclination between the superior and inferior strata is expressed by the term *unconformity*, and the rock is said to lie *unconformably* upon the lower.

Principal epochs of convulsion.

By pursuing this investigation in different situations, we find that these internal movements or convulsions happened at intervals during the whole period of time occupied in the deposition of the strata. The most prevalent and remarkable cases of dislocation and unconformity are however observable: 1. immediately after the deposition of the slate series; (*Transition series* of Werner;) 2. after the accumulation of the coal system; 3. after the deposition of the oolitic rocks; 4. after the deposition of the chalk; and 5thly, one of the most recent probably of all, after the completion of almost all the formations above the chalk. It is not to be supposed that all even of these principal cases of dislocation can be recognised in every Country; on the contrary, the subterranean forces appear frequently to have shifted their points of action.

We shall have occasion to show, while speaking of the organic remains, that there is sometimes observed a singular harmony between these periods of extraordinary internal disturbance and the several epochas when the different races of animals and plants came into existence; and it is not unreasonable to suppose, that in this manner it may be hereafter found possible to establish such a relation between the internal and external condition of the Earth, as to afford the greatest assistance towards defining the agencies which have produced changes so extensive and repeated in both.

Proximity of mountains.

At present, restricting ourselves to the phenomena of elevation and disruption of the strata, we shall carry our inductions one step further for the purpose of proving what was before announced, *viz.* that these disturbances were connected with the effects of internal fires.

We shall assume then that granitic, and basaltic or trappean rocks, and others exhibiting the same phenomena, were crystallized from a state of igneous fusion, and were, sometimes in a fluid and sometimes in a solid state, impelled upwards from the interior of the Earth, as analogous substances are now raised fluid through volcanos, or lifted solid by earthquakes.

In proportion as we approach the mountains where the greatest violence was exerted to break up the strata, raise the granite, and inject the basaltic dykes, we find the dislocations increased in number and importance, and the confusion of the stratification more prevalent.

The central nucleus or axis of many mountain districts is a mass, or a series of masses of granite and other unstratified rocks, from which on all hands the strata are found dipping at high angles. In such cases there can be little room to doubt that the elevation of the mountain ranges and the disturbance of the strata, was occasioned by the same violence which uplifted the granite. See pl. i. fig. 8.

The area of granite disclosed between the opposite slopes of slate, is indefinite, sometimes very large,

sometimes very small, sometimes it is entirely covered over by the slate, which it has uplifted, but not perforated. The general analogy in the composition of mountains, in the strata which surround them, and in the dislocations which abound in their vicinity, prove that one common cause, the force of subterranean fire, has produced all the phenomena in question.

Basaltic rocks frequently, perhaps generally, show themselves in situations removed from the granitic regions, on the flanks of mountains and in lower ground. In numerous instances, basalt fills up the fissure between the elevated and depressed portions of dislocated strata, and as it cannot be doubted that such a fissure would soon have been filled up by other substances, it is clear that the melted basalt was injected nearly at the same time as the dislocation was produced; that is, that both were local effects of violent internal heat.

Analogy of mineral veins and trap dykes.

So great a general analogy prevails between some mineral veins and basaltic dykes, that in almost all hypotheses their origin has been assumed to be the same. Both in the same manner divide the strata; in both the materials are crystalline, generally such as are not known to be producible from water, and arranged according to entirely different laws from those which regulate deposits from water. It seems besides almost inconceivable that materials of such various Specific Gravity and Chemical affinities should be either soluble at once in water or capable of being introduced by this process at different times; on the contrary, all the circumstances agree in claiming for such mineral veins the same origin as basaltic dykes, the igneous origin of which is supported by the strongest possible arguments. We shall, however, discuss the history and origin of mineral veins more at large in the Chapter on Plutonic Products, and we shall then notice a variety of phenomena concerning them which can with difficulty be explained in the present state of our knowledge of Chemistry. That part of the history of mineral veins and metallic substances in general, which is inseparable from the consideration of the rocks in which they occur, will be treated of while speaking of the several strata in succession.

Disruptions of strata, a part of the general plan of terrestrial adaptations.

This elementary statement of the characteristic effects of subterranean convulsions upon the preconsolidated strata, must not be closed without noticing an important beneficial result of them upon the condition of mankind. The frequent use of the terms convulsions, dislocations, and other such phrases in Geological Treatises, may, perhaps, lead the inattentive reader to imagine that Geologists are of opinion that the laminated crust of the Earth, which had been constructed with so great harmony and order, was afterwards subjected to accidental injury, left to the violence of forces not contemplated in its formation, and the original plan of its fabric destroyed by unforeseen convulsions. How false a notion is this, and how unjustly would Geologists be accused of ignorance in this respect! They know well that without the effects, which are called convulsions and dislocations, the plan of the terrestrial creation would have been incomplete, the Earth not adapted, as it is, for the residence of men and the exercise of human intellect, which in all this seeming confusion can discern the progress of an uninterrupted plan, and even trace special provisions in favour of mankind. Whether we regard the mere animal nature of Man, or consider him with reference to those glorious endowments which lift him above the brute, and enable him to contemplate the past and anticipate the future, and thus to expand his intellectual existence through all periods and over all subjects, we shall find in the broken stratification of the Earth, the most remarkable attention to his Physical and Mental constitution.

Elevation of continents.

How universal are the benefits which are conferred on Commerce and the Arts of life, by the variety of substances obtained from the Animal Kingdom, cannot require to be stated; for without this variety, neither Commerce nor the Arts of life could exist. Some faint idea of the state of a Globe which did not show this variety, may be conceived by viewing the condition of the sandy deserts of Africa, and abstracting from their solitary desolation the assistance rendered by more favourably situated Countries. Now all that variety of mineral products existing in the Earth, stored up in that inexhaustible repository to supply many regions through many national revolutions, would have been made in vain, and for ever hidden from the eyes of men, but for these very convulsions and dislocations in the strata. What else has raised our mountains, divided our seas, and given currents to our rivers, and by so doing established upon the Globe those varieties of soil, local climate, and other conditions to which the organic wonders of Creation are most evidently adapted? What other means have been employed to produce the natural, harmonious, and mutually dependent relation of plants and animals on the land, in the streams, and in the sea? Without these disruptions, the Earth would still have been uniformly covered by shallow waters; or if some part rose above it, must have been a barren waste, or a monotonous surface on which the living wonders of Nature, according to the actual plan of Creation, could not have appeared. It is, therefore, evident, that as one of the means employed by the Creator in the accomplishment of his works, the agency concerned in producing the actual condition of the terraqueous surface, and thereby regulating the leading phenomena of organic and inorganic Nature, is a fit object for the special study of Geologists.

Exhibition of useful minerals.

It is not only in the elevation of continents, the varying height of mountains, the division of the sea, and similar striking effects, that we see the utility of the combination of subterranean igneous with superficial aqueous agency. Every coal-field in the known World proves distinctly the utility of even the minor dislocations, which in our imperfect language are called "faults" in the strata. The universal effect of these "faults" is to multiply the visible edges of the strata, by bringing them more frequently to the surface, in consequence of which there is, in the first place, the greater chance of discovering the materials of the Earth; and, secondly, the greater facility of working them. Other advantages of this kind will immediately suggest themselves to the attentive reader.

But all advantages to Commerce and the Arts of life sink into nothing when compared with the effect which the Human Mind experiences from contemplating the monuments of past conditions of the Globe, which the uplifting of the bed of the sea, and the dislocations of the strata, have brought to light. All Nature is a glorious book, which men are incited to read, in order to know and communicate with its Author, a mirror in which the Almighty and the Infinite is faintly typified in the vast and the diversified; and in this respect, Geological monuments are distinct, impressive, and, in reference to the earlier epochs, unique. But, if we have been conducted by long labours to some real knowledge of the internal constitution of the Globe,

and familiarized with the conception of many revolutions of created Beings on its surface, in accordance with a long sequence of Mechanical and Chemical operations; and if we have thus extended the conviction of the unceasing care and comprehensive benevolence of the Divine Being to the most remote epoch which our limited intellect can reach; all this is owing, in a certain sense, to the convulsive movements originating below the crust of the Earth. Let it not, therefore, be supposed, that, because of the contracted scale of the Human Mind, which can see only in succession what to a greater Intelligence is contemporaneously evident, Geologists are obliged to speak of certain phenomena as *accidents* with reference to others, which are connected therewith by ways unknown to us, that they are so blind as not to see in all the diversified operations of Nature, the effects of One predisposing and directing Cause.

Internal Structure of Rocks.

Joints in different rocks.

All rocks, whether stratified or not, are naturally divided by fissures, passing in various directions, independent of the strata, into masses, which are of different form in dissimilar rocks, and are accompanied by circumstances deserving more attention than has yet been bestowed upon them. The fissures or planes of parting between these masses are called *joints*. Most frequently their direction is nearly vertical to the planes of stratification, where such exist, and they divide the rock into cubical, rhomboidal, or prismatic portions, blocks, pillars, or columns. It is owing to their various direction and frequency that different rocks assume such characteristic appearances, and may thus be often and readily distinguished when seen at a distance or shadowed in a drawing.

Some rocks have very numerous, approximate, and closed joints, as shale, some kinds of slate, and laminated sandstones; in others, as limestone, the joints are less frequent, and more open.

In coarse sandstones, they are very irregular, so that quarries of this rock produce blocks of all sizes and forms. From this cause, coarse sandstone rocks show themselves against the sea, in precipitous valleys, or on the brow of hills, in rude and romantic grandeur. The wild scenery of the Peak of Derbyshire, Brimham Crags, and Ingleborough in Yorkshire, derives attractive features from the enormous blocks of millstone grit; and the magnificent rocks which stand upon the hills and overlook the Vale of Wye, are composed of a somewhat similar material.

In clay, vertical joints are numerous, but small and confused, whereas in indurated shale they are of extraordinary length, very straight, and parallel, dividing the rock into rhomboidal masses. This may be well studied in the shale, which alternates with mountain limestone, at Aldstone Moor in Cumberland. Rhomboidal joints are frequent and very regular in coal.

In limestone the vertical joints are generally regular, and arranged in two sets, which cross at nearly equal distances, and split the beds into equal-sized cuboidal blocks; and thus the mountain limestone is found to be divided into vast pillars, which range in long perpendicular scars down the mining dales of the North of England.

In slate districts, the joints, more numerous and more regular perhaps than in any other known rock, have almost universally a tendency to intersect one another at acute and obtuse angles, and thus to dissect whole mountains into a multitude of angular solids, with rhomboidal or triangular faces, which strongly impress upon the beholder the notion of an imperfect crystallization, produced on these argillaceous rocks since their deposition and consolidation, by some agency, probably heat, capable of partially or wholly obliterating the original marks of stratification.

Vertical joints are frequent in granite, and appear to have definite directions. The trihedral and polyhedral vertical prisms of basalt, and some other igneous rocks, coupled with their regular transverse divisions, seem to give us the extreme effect of regularity in the division of rocks by the process of condensation, from the state of igneous or aqueous expansion.

General cause of joints and fissures.

That contraction after partial consolidation of the mass is the general immediate cause of the numerous fissures of rocks, may easily be proved by a variety of facts observed in conglomerate rocks, where pebbles, and in others where organic remains are *split* by the joints, but cannot surely require argument. According to the circumstances of the case, this process has produced in basalt, slate, and coal fissures so regular as to give to the rock a largely crystalline structure, but left in sandstone mere irregular cracks.

From Mr. Gregory Watt's experiments on fused basalt, and some other notices by different authors, we know that a continued application of even moderate heat to a previously solidified body, may be sufficient to develope in it new arrangements of the particles, new crystalline structures, new Chemical combinations, and to cause a real transfer of some of the ingredients from one part of the mass to another; from many independent facts it is inferred, as a matter of certainty, that all the strata have locally, and the lower ones perhaps universally, sustained the action of considerable heat, since their first deposition: we seem, therefore, to be possessed of the clue which is eventually to conduct us to a thorough knowledge of the cause of the different structures observable in rocks independent of their stratification.

But though heat be taken as the leading cause of these effects, it is by no means inconsistent to suppose that some other independent agent, as, for example, Electricity, might be concerned in modifying the result. From all the recent discoveries in Electricity, it appears more and more certain, that this universal agent is excited in every case of disturbance of the Chemical or Mechanical equilibrium of natural bodies, and it is especially, and very sensibly, excited by unequal distribution of heat. Professor Sedgwick's suggestion with reference to Mr. Fox's electro-magnetic experiments on the mineral veins of Cornwall, that Electricity was probably concerned in the original production of those veins along which it now circulates, may be justly extended to the joints of rocks; in the study of which the writer of these remarks has found abundant reason to believe that the theory of the production of mineral veins is inseparable from that of the joints and fissures, in *some of which* the metallic substances are deposited.

Direction of fissures.

In examining with attention a considerable surface of rock, it will be found that amongst the joints are some more open, regular, and continuous than the others, which occasionally stop altogether the cross-joints, themselves ranging uninterruptedly for some hundreds of yards, or even far greater distances. There may be more than one such set of long joints, and, indeed, this is commonly the case, yet, generally, there is one set

more commanding than the others, more regular and determined in its direction, more completely dividing the strata from top to bottom, even through very great thicknesses, and through several alternations of strata. For example, there is a peculiar character of joints in each of the principal strata of the mountain limestone series, limestone, sandstone, shale, and also in the sandstones, shales, and coal of a coal district, yet, throughout the whole of Yorkshire, all these rocks are divided by the *master-joints* passing downward through them all in nearly the same direction North by West, and South by East. These master-joints, called *slines, backs, bords*, &c. are perfectly well known to the workmen, as well as some other very important yet less certain and continuous fissures passing nearly East North-East and West South-West. It is according to such joints that the experienced collier arranges his workings, and the slater and quarryman conduct their excavations. Now surely nothing can be more certain than the inference, that some very general and long-continued agency, pervading at once the whole mass of these dissimilar and successively deposited strata, was concerned in producing this remarkable constancy of direction in the fissures which divide them all. The utter deficiency of recorded observations prevents any further illustration of this important subject by reference to other districts, but it is obvious that a great principle in the construction of the Earth is here indicated, which must eventually have an important influence on Geological Theory. In the mean time we may remark, *first*, that these prevalent directions of North by West and East North-East, are those of the principal *mineral veins* and cross courses in the North of England, and that they are also admitted to be very prevalent in the Southern and Western mining Countries; *secondly*, that these directions are wholly uninfluenced either by the *declination* of the strata, or by the numerous *dislocations* to which they are liable. Whatever be the direction of the dip, how frequent soever the faults, the lines of the great joints are the same. These lines are frequently the cause of particular courses in rivers, long scars on mountain sides, and subterranean channels for water. Faults, and dykes, and mineral veins very frequently pass along them, and there is little doubt that the diligent study of them will be found to throw a new light on some of the most mysterious phenomena of Geology. See pl. i. fig. 9.

In a recent Paper on the cleavages of granite in Cornwall by Mr. Enys and Mr. Fox, these cleavages are proved to follow certain lines of *definite* direction, like the well-known cleavages of slate.

Local changes of internal structure.

Though a little out of place, we cannot forbear to add here a short notice of facts known in Swisserland, which distinctly prove one of the effects of heat upon common argillaceous shales, to be the alteration of its structure, so as to give a real vertical cleavage to a mass of horizontal laminæ of clay, as well as that induration which belongs to slate. The lias shales of the Alps are so altered by proximity to the igneous rocks of that region, that in several places in and near the Valley of Chamouni, they are commonly mistaken by modern tourists for genuine slates of the primary system, and were always described as such by the older writers. How plainly does this teach us that the joints, cleavages, and other peculiarities of their structure, not produced in rocks by water, nor coeval with their deposition, have been occasioned chiefly by the agency of subterranean heat. What powerful aid does this generalization give toward explaining many phenomena heretofore despaired of in Geology.

Mineral Composition of Strata.

Water is both a Chemical and a Mechanical agent. Under different circumstances at certain temperatures, by the help of other ingredients, as acids or alkalies, various mineral substances are dissolved in it. When, by evaporation, loss of heat, or a change in the composition of the liquid, these substances are no longer capable of remaining in solution in it, they separate in a crystallized form, or fall down, and the sediment which they occasion is called a precipitate.

By such processes lime, magnesia, and other earths and metallic oxides, are first dissolved in water, and afterwards separated from it. We find these processes, in the present order of Nature, chiefly concerned in producing calcareous marls and irregular accumulations of limestone, in lakes and in the course of certain streams and at the mouths of some rivers. So in more ancient times, the most abundant Chemical deposit from water was limestone.

The *Mechanical agency* of water is manifest at the present day in removing materials from one place and accumulating them in another. Thus pebbles and sand and clay are transported by the tides and by rivers, and accumulated in low situations in regular layers, miniature representations of those thicker strata of the same ingredients, which compose the crust of the Earth. And as at the present day some materials are transported further by water than others, and consequently more rounded by attrition, so the materials of the interior strata are likewise more or less worn and rounded, in proportion to the distance they have travelled and the friction they have suffered.

In many situations Chemical and Mechanical products are occasioned successively by the same waters, just as, in the older strata limestones and sandstones alternately prevail. We see, therefore, that the ancient deposits from water, which form layers several miles thick around a great part of the Globe, are not essentially different, except in degree, from the lesser deposits now formed beneath the tides from the sea and the streams from the land.

The Chemical stratified deposits are principally limestones, composed of carbonates of lime and magnesia, and salt rocks characterised by muriate of soda. This is not the place to discuss points of Theory, and we shall therefore speculate no further at present on the origin of these deposits than to say, that if by any means a large supply of an alkaline carbonate, as carbonate of soda, for instance, was diffused through the sea, the effect would be a precipitation of carbonate of lime and carbonate of magnesia, which would be accumulated into strata upon the bed of the sea in thickness proportioned to the quantity of the muriates decomposed, while the supernatant liquid would be found highly charged with muriate of soda, or common salt. If the alkali were only locally diffused, the deposit would be contracted, if generally, the strata might be very extensive.

The *Mechanical deposits*, or strata, composed of earthy materials, are distinguished by the coarseness or fineness of the ingredients and by the nature of these ingredients. When the materials are of unequal fineness, and some of them are large, rounded pieces, the rock is called a conglomerate; pieces not so large constitute a sandstone, very fine particles clay. The fol-

Geology. Ch. I.

lowing scale will convey some notion of the gradations of size in the ingredients of Mechanical deposits.

Very fine particles generally containing 20 to 30 parts of alumine	Clay, marl, shale, and slate.
Mixture of clay and sand	Sandy clay.
Sand with some clay	Argillaceous sandstone.
Small fragments of hard silicious minerals..............	Sand, sandstone.
Sandstone including pebbles ...	Millstone grit.
Large pebbles united by sandstone or clay	Conglomerate, or puddingstone.
Pebbles disunited.............	Gravel.
Stony fragments reunited	Breccia.

Ingredients of mechanical strata.

Considered with reference to the *nature* of the ingredients which compose them, Mechanical strata form another scale.

Thus gneiss, one of the oldest of these strata, is a compound of the same ingredients as granite—quartz, felspar, and mica; but these minerals, instead of being amalgamated (so to speak) together by crystallization, are accumulated in successive laminæ more or less regular. Gneiss, therefore, differs from micaceous sandstone much less than is commonly imagined, and often has no other permanent distinctive character, than that presented by the peculiarity of its composition.

Sandstone is generally an aggregate of small fragments, or worn crystals, of quartz, with or without any argillaceous, or calcareous, or irony cement in the interstices, with or without any mica in the partings. Sometimes it very evidently contains rolled and broken pieces of crystallized felspar, such as fills the Pyramids around Mont Blanc, or the granite of Cumbria and Scotland. There is, therefore, every reason to conclude, that coarse sandstones like the millstone grit, as well as gneiss, have been derived from the waste of ancient tracts of granite.

Some beds of sandstone at Oban in Argyleshire appear to have been formed from the granular fragments of disintegrated greenstones. Sandstones sometimes extend over vast districts, and during the whole range are characterised by some remarkable mineral ingredient; as for instance, the green sand of England, France, and Swisserland, which is distinguished by the presence of a peculiar green mineral. (Glauconite.)

Conglomerates, on the other hand, are generally constituted of fragments from the neighbouring mountains. Thus the red sandstone of the Vosges mountains contains quartz pebbles derived from the slate rocks of the vicinity; the old red conglomerate of England varies in its composition according to its locality; that of Herefordshire contains much quartz, that of Cumberland is filled with pebbles of slate.

Whole series of strata.

The whole series of stratified rocks then consists of alternate deposits of limestone, sandstone, and clay, with few layers of coal, rock salt, flint, iron ore, &c. The modes of alternation are different in different parts of the series, and in different situations. Thus what is called the transition limestone is enclosed between beds of slate, the carboniferous limestone alternates with sandstone and shale, the lias limestone lies in marly clays, the coralline oolite is enveloped in calcareous sandstone. Generally, the different strata are distinguishable by their mineralogical characters; but not always. When the circumstances of the deposit were nearly similar, as in the accumulation of the carboniferous limestone and some of the oolites, the strata are remarkably alike; and often particular beds of one rock are scarcely to be distinguished from beds of another rock. Thus some beds of lias are scarcely to be known from some calcareous layers connected with the Bath oolite, while other portions of the same rock strongly assimilate to the carboniferous limestone. The old red sandstone and the new red sandstone formations are very much alike; it would be difficult by mere mineralogical methods to discriminate the clays which separate the oolites, and many sandstones of very different epochs are almost undistinguishable. Hence we may infer that nearly the whole series of strata is the result of many repetitions of similar Mechanical and Chemical agencies operated by the same waters.

Alternation of beds.

When sets of strata are in contact, as for instance limestone lying upon sandstone, it often happens that while the limestone above, and the sandstone below, are unmixed with other matter, there is a middle set of beds composed of alternate layers of the sandstone and limestone. Thus let a be the coralline oolite of England, and b calcareous sandstone beneath; the middle beds $a' a'' b' b''$ are alternately oolite and sandstone. See pl. i. fig. 10.

In such a case, therefore, the two strata are said to *exchange beds*, or to be subject to *alternation* at their junction, and the phenomenon seems to have been occasioned by temporary cessations of the deposit of sandstone during the commencement and progress of the deposit of limestone.

Gradation of beds.

In other instances the two strata *pass into one another* by imperceptible *gradation*; as for instance, the Oxford clay of the Yorkshire coast graduates into the calcareous grit above so completely, that the bluish colour of the crumbling shale below is shaded off without any hard line into the yellow solid beds of grit above. See pl. i. fig. 11.

In either case it seems quite evident that no considerable break or interval of time happened between the different contiguous deposits, one bed was no sooner formed than another was laid upon it; and by careful study of these phenomena it appears that, bed by bed, and rock after rock, the whole series of strata even to miles in thickness were successively and almost unremittingly accumulated, and buried the shells and other organic Beings, which were then living in the water, or drifted into it from the land; such are, therefore, the best witnesses of the lapse of time, and of the changing condition of the land and water during the deposition of the strata.

Proportions of Chemical and Mechanical deposits.

Assuming limestones to be Chemical, and sandstones, clays, &c. to be Mechanical deposits, and putting for the present out of consideration the organic remains, which so much abound, especially in calcareous strata, we shall be able by comparison of the thickness of the several rocks to present a tolerably accurate notion of the relative proportions of Chemical and Mechanical deposits. The greatest obstacles to accuracy exist amongst the primary strata, whose thickness is exceedingly uncertain, and indeed often hardly to be determined at all.

If we take our examples of these strata from the Island of Great Britain, it may, perhaps, be found a sufficient approximation to the ratio now sought to say the Mechanical to the Chemical deposits of water are:

In the Primary Series, as	500 : 1
Carboniferous System....	10 : 1
Saliferous System	5 : 1
Oolitic System	4 : 1
Cretaceous System	2 : 1
Tertiary System.........	10 : 1

Geology. Ch. I.

From this comparison it would appear that the ratio of Chemical to Mechanical strata is greatest amongst the secondary deposits, andj least amongst those of the primary periods; a circumstance on which depend principally the well-marked general characters of the secondary series of rocks. It should, besides, be observed, that calcareous matter very finely divided exists in nearly all the sandstones and shales of that series, and sometimes so abundantly as to change, locally, lias shale into argillaceous limestone, and calcareous grit into arenaceous limestone, or coarse oolite. In secondary strata, the great preponderance of limestones almost invariably attracts the attention and directs the classification, and thus it happens that while numerous layers of clay and sand pass nearly unobserved, or are merely noticed as *interpolated beds*, almost every calcareous bed has its characteristic local name. The almost universal diffusion of calcareous matter through the mechanical strata of this large class, combined with the greater regularity and persistence of the limestones, generally impresses on the attentive observer a peculiar theoretical notion as to the cause. He soon learns to consider the operations by which sandstones and clays were accumulated as of short duration, and intermitting action, like the periodical floods of a river, or some less regular inundations; while the production of limestone is regarded as the result of one continuous and almost uninterrupted series of Chemical changes. This opinion, strengthened by the curious gradations between the calcareous and the sandy or argillaceous laminæ, and by the frequent alternation amongst even their thinnest portions, derives very plausible arguments from the distribution of organic remains through the several strata. In some cases these teach us plainly that sandstones, even of great thickness, were the products of temporary and often of very local floods, which swept down from the land the scattered spoils of the animals and plants then in existence; but, tried by the same tests, the calcareous rocks appear to have been of slower and more equable production, in clearer and more tranquil waters. Is not this exactly in harmony with the present system of natural operations?

Condition of Organic Remains.

What organic remains occur in the Earth.

The fossil remains of ancient plants and animals have been the theme of admiration for the learned and the vulgar in every Historical Age. The difficulty of understanding how the shells of the sea and the plants of the land could be inclosed in hard rocks, in prodigious abundance and of exquisite beauty, led Plot and Llwyd, and even partially Ray and Lister, together with some continental writers of eminence, to adopt a most strange hypothesis. Plot advanced the extreme absurdity that these beautiful monuments of the ancient condition of the Earth had in fact never been shells or plants, but were merely *lusus naturæ*, deceptive resemblances produced by some plastic power in the interior of the Earth. Swift well ridicules this notion of *lusus naturæ* in his Voyage to Brobdignag.

This ridiculous fancy has long since become obsolete, and the "formed stones" dug out of the bowels of the Earth are now recognised as the original inhabitants of its primeval land and water.

The differences of condition between them and analogous living objects, the mode of their conservation, the manner of their distribution in the Earth, the relative periods of their existence and destruction, constitute a vast, lucid field of research, through which many avenues are already traced toward the secret powers which presided over the formation of the Earth.

Terrestrial Plants abound in certain strata, especially in the coal districts, where the seams of coal are nothing but vast layers of vegetables swept down into estuaries or lakes, and there covered by sand and clay, and changed by Chemical depositions.

Zoophytes both stony and flexible, many of them belonging to genera now in existence, fill our limestone rocks with their most delicate and beautiful organization; with them lie abundantly columns of crinoidal animals, and crusts and spines of echini.

Molluscous Animals are now the most numerous of all the tribes of Beings which overspread the bed of the sea, and their shelly coverings are also the most abundant of all the organic fossils.

Of the Articulated Animals, the most abundant remains are lobsters and crabs, and other crustacea, analogous to existing types; besides trilobites and others to which nothing similar has yet been found in the modern ocean. Fossil insects are very rare; and confined to almost a few comparatively recent deposits from fresh-water.

What portions of the original structures are preserved.

No one acquainted with the structure of the invertebral Animals previously mentioned, can view their crusts, shells, and other hard appendages in the fossil state without being struck on the one hand with the wonderful perfection of all their minutest organization, and on the other with the uniform and almost total absence of their soft parts. The bodies found "petrified" in the rocks were originally durable. Similar substances are now capable of conservation in our cabinets: but the softer animal parts which they protected—the muscles, the viscera, and even the ligaments—have almost uniformly disappeared. Hence it appears a just conclusion that the process of petrification, the substitution of mineral for animal matter, was slow and gradual.*

The same result follows a similar examination of the fossil reliquiæ of vertebral Animals. For though we find in tolerable plenty the bones and teeth of fishes and reptiles, the skin and other softer parts are usually deficient. The bones of birds are excessively rare, and those of mammalia are mostly confined to the least ancient of all the Neptunian deposits.

In what state imbedded.

In consequence of this decay of the softer parts, many of the hard parts of Animals are found disjointed and separate. Crusts of lobsters, bivalve shells, vertebral columns, originally bound together by perishable ligaments, are very generally found in detached portions, precisely as happens to similar objects at the present day; and generally this is all the injury they have sustained. The delicate striæ, sharp spines, and other ornaments, are usually so well preserved that no one can believe that they were ever removed far from their native haunts. They were, in fact, quietly buried on the bed of the sea; living or dead, entire or decomposed, just as such Beings are found at the present day, when by any method the bed of the sea can be examined.

And just as at the present day where currents run strongly in the sea, shells are worn by friction in the

* The ligament of *Cardium truncatum* is preserved in marlstone at Rosebury and Staithes in Yorkshire, and impressions of the *Arms of Cephalopoda* are found in the oolite of Franconia.

Geology. Ch. I.

sand and by beating against one another, and trees carried down by rivers are scattered in fragments; so in certain of the old strata we find similar proofs of rapid currents from the land, and temporary turbulence in the primeval ocean.

All the accidents of imperfection and disunion of parts happened, of course, before the organic bodies were enveloped in the earthy deposits.

Subsequent changes of composition.

The changes by which they have been converted to petrifactions did not, probably, commence till after they were thus enclosed.

These changes in the substance of the fossil reliquiæ are different according to the original nature of these bodies, the kind of matter in which they are enveloped, and the other circumstances by which they were surrounded.

We shall make some remarks on the conservation of the principal classes of organic fossils in the different kinds of matter.

In plants.

Dried vegetable substances may be considered as compounds of carbon, oxygen, and hydrogen, with small and variable proportions of other substances.

Carbon	40 to 55 per cent.
Oxygen......	40 to 50
Hydrogen	about 5

Of these ingredients the most volatile parts, *viz.*, the oxygen and hydrogen, seem, in many cases, to have vanished, but the carbon generally remains, and is either almost pure, as in some kinds of coal; mixed with bitumen, as in jet and most coals; mixed with carbonate of lime, as in the remains of coniferous wood in the lias and oolite; or blended with flint or pyrites in those and other strata. Generally, as might be expected, the vegetable substance is most completely disguised by earthy admixtures in porous strata, such as oolite or sandstone; and, on the other hand, the original carbonaceous skeleton of the plant is preserved with the least change in close, compact materials like clay, shale, or ironstone. This is strikingly exemplified in the coal-districts, where ferns and other plants which lie in the shales are changed to bright inflammable coal, while the very same species in coarse gritstone are represented only by a brown, ferruginous stain. Coal is most evidently a product on a large scale, precisely identical with the thin filmy remains of ferns and reeds which accompany it. A vast mass of plants accumulated beneath the ancient sea, or in sea-like lakes, was covered up and buried by successive deposits of sand and clay, and under this heavy pressure, and hermetically sealed, Chemical decomposition went on, and a new Chemical product, coal, was elaborated; which, upon analysis, is found to contain the usual ingredients of vegetables, in proportions no otherwise different than was to be expected from the loss of some of the more volatile parts.

In this respect, coal exhibits many variations. That of Kilkenny, for instance, has only four per cent of volatile matter; Cannel coal has about fifty per cent.; the Kilkenny coal contains ninety-two per cent of carbon, common coal about seventy per cent. carbon, and thirty per cent. oxygen and hydrogen.

In corals, shells, crusts.

The internal and external hard parts of invertebral animals, zoophytes, mollusca, and articulosa, are much allied in composition. They generally contain the same durable and the same perishable parts; carbonate of lime, alone or with a small admixture of phosphate of lime, gives them firmness, and the flexibility which some of them possess is derived from gelatine.

Geology. Ch. I.

The process of petrification consists in the loss and replacement by a different substance of one or other of these ingredients. The first degree of change which these fossils have experienced, is when the coralline or shell retains not only its external figure and appearance, but even its internal texture, and almost all its original substance. Such specimens look as if obtained from the sea-shore in a dead state, with no other apparent loss than that of colour and brilliancy. This state of conservation may be said almost to characterise the organic remains of the strata above the chalk.

Loss of colour, &c.

The next step in the process of petrification is illustrated by many shells which lie in the gault and other clays; they have lost their gelatinous portion, and are, in consequence, become light and friable, but have not received into their pores any extraneous earth.

Loss of gelatine.

The third variation is occasioned by the gradual substitution of an extraneous substance, as flint or pyrites, into the pores left by the decay or waste of the original body; thus the fibres of wood and sponge, and the plates of corallines and shells, have been changed by little and little into a different substance, which often represents with most faithful accuracy the minutest structure of the original. It is evident, therefore, that this great change was accomplished gradually, the new particles taking successively the place of those removed by decomposition.

Insinuation of new matter.

These processes of decomposition and substitution of new ingredients, which probably commenced at the periods when the several fossils were imbedded in the rocks, are to this day continued, and often exhibited with remarkable energy. Those products of modern operations of Nature which go under the vague name of recent petrifactions are so various in their character, that a detailed study of them, in relation to their accompanying circumstances, could not fail to furnish data for explaining some of the most remarkable stages in the process of mineralization, to which organic bodies have been exposed in the Earth. In proof of this, we shall content ourselves at present with putting in comparison a well-known peculiarity in the mode of conservation of certain fossils, and an instance of the same singularity in recent petrifactions. It is often to be noticed that while the external cell of an ammonite, or the larger part of the spiral cavity of a melania, is filled by the coarse matter of the enveloping rock, the closed chambers of the former, and the smallest volutions of the latter, are filled with crystals of calcareous spar. The well-closed shells of productæ, terebratulæ, &c. are often lined internally with calcareous spar, quartz, or even galena, while this never happens, perhaps, to shells whose valves did not fit very exactly. In fossil wood it happens very often that the external parts are merely jet or coal, while the central portions are changed to carbonate of lime; and, in general, all these examples appear to agree in proving that the mineralizing substance was transferred to its repository in the innermost cells and smallest pores by a kind of secretion, quite through solid septa of shell, and considerable thickness of even dense stone. The recent petrifactions of hazel-wood and nuts, from the alluvium of Ferrybridge in Yorkshire, (*Phil. Mag.* 1828,) prove that the same remarkable transfer of particles through other substances, with the same elective attraction for these particles possessed by the finest textures and smallest cavities, accompany the ordinary modern aqueous deposits of carbonate of lime. In the alluvium of

Analogous modern processes.

this place, a certain part of a large collection of hazel-wood and nuts was found mineralized by a subterranean spring from the neighbouring limestone, and it was remarkable that the central woody core of a hazel-branch or root was wholly converted to stone, while the bark and outer layers of wood were unchanged, the kernel of the nut was petrified within its brown unaltered membrane, and the internal fibres of the shell within the still woody surfaces.

Dissolution of shells, corals, &c. The fourth condition is exemplified in limestone and sandstone rocks, from which the whole of the substance of shells, corals, &c., has been dissolved and carried away by water. In consequence, a cavity is left in the rock bearing the *impression* of the exterior of the shell or coral, and in this cavity is a *mould* or *cast* of the interior. Thus the "screwstones," as they are called, have been cast or moulded in the cavities of crinoidal columns.

Replacement of shells, corals, &c. The most extreme case of mineralization or petrifaction is produced by a process in addition to that just described, when the cavity left by the removal of the shell or coral is again filled up with crystals of calcareous spar, deposited by water filtrating through the stone. Sometimes, only a few crystals connect the inner mould or cast to the exterior impression, but generally, the whole cavity is filled by the spar, which thus represents truly the shape of the original body, but displays no trace whatever of its internal texture.

Dependence of these changes on the nature of the rocks. There is in general a certain accordance and relation between the condition of organic fossils, and the nature of the rock which incloses them. In the green sand almost all the shells are silicified, in the oolitic rocks many are changed to calcareous spar, in the clays very slight changes have happened to any of the organic remains.

On the other hand, the original nature of the organic substance has very much influenced its mode of conservation. Echinidal and crinoidal remains are almost invariably converted to a peculiar kind of opaque, calcareous spar, in whatever strata they occur; gryphææ and astrææ retain their laminæ, inocerami and belemnites their fibres.

Remains of vertebrata. We come now to the vertebral division of Animals. Their soft portions have perished, but their teeth, bones, and scales remain, either connected or separated in consequence of the decay of the ligaments, cartilages, &c.

The hardening ingredient of bones is principally phosphate of lime, that of teeth is a mixture of phosphate and carbonate of lime. It is generally the fact that their gelatinous or membranous portion has been diminished, and their earthy admixture increased, by the subterranean Chemistry to which they have been subjected, and, in consequence, their Specific Gravity is much augmented.

Distribution of Organic Remains.

Number of species. The researches of modern Naturalists have been singularly successful in bringing to light a vast number of new species or supposed original types of organization. The catalogues of living plants and Animals have been enormously lengthened in consequence of more rigorous investigations among the smaller tribes. In like manner the number of known organic fossils has been of late year[illegible] greatly augmented, that in some departments the[illegible]ly equal, and, in others, exceed the living ranks of [illegible]tion. In Great Britain alone, 1500 species of organic remains have been well described and figured; and it is probable that the numerous tribes of undescribed zoophyta, mollusca, crustacea, and plants, will swell the catalogue to 2500 species at least. An equal number of other kinds adorn the cabinets of Continental Europe. Generally speaking, the principal deficiencies in the catalogue of fossils, as compared with that of living organic forms, are found in the aerial and terrestrial races.

Insects, birds, land reptiles, and mammalia are the rarest of fossils. We are, however, not to conclude that the ancient land was uninhabited by those tribes, because we do not find their remains in the strata which were formed on the bed of the ancient sea. Such remains are very rarely carried down and buried beneath modern lakes, and therefore were much less likely to be entombed beneath the deposits of the ocean.

Plants. In the following Table, M. Adolphe Brongniart compares the extinct flora of the Ancient World at four several periods with the vegetation which now covers the Earth. The general proportion is about 100 living plants to one fossil one.

	Première Période.	Deuxième Période.	Troisième Période.	Quatrième Période.	Epoque Actuelle.
1. Agames	4	5	18	13	7.000
2. Cryptogames cellulenses	—	—	—	2	1.500
3. Cryptogames vasculaires	222	8	31	6	1.700
4. Phanerogames gymnospermes	—	5	35	20	150
5. Phanerogames monocotyledones	16	5	3	25 ?	8.000
6. Phanerogames dicotyledones	—	—	--	100 ?	32.000
Indéterminées	22	—	—	—	—
	264	23	87	166	50.350
	$\underbrace{\qquad\qquad\qquad}_{540}$				

The immense disproportion between the numbers of fossil and living vegetables will probably not justify the inference that in ancient periods only a few species of plants covered the surface of the Earth. Only a small proportion of the vegetable tribes now growing upon the Earth are swept down into the sea, comparatively but a very trifling number would be carried there by even the most violent floods, and therefore the few hundred species of fossil plants are probably only a very small selection from the numbers that really covered the Earth. Nevertheless these few relics may be reasonably supposed to have been amongst the most abundant of the plants then in existence, and may be usefully employed in characterising the several periods of deposition.

Thus it appears that in the most ancient of the four periods defined by M. Brongniart, ending before the deposit of magnesian limestone, the most abundant fossil plants belong to the vascular cryptogamic class, including the natural families, ferns, equisetaceæ, lycopodiaceæ, &c., that in the third period, which includes the oolitic and cretaceous rocks, cycadeæ are especially numerous; and in the fourth or tertiary period the more complicated dicotyledonous plants appear, and thus gradually conduct us to the vegetation of the present day.

Zoophytes. Zoophytes, the first tribe of Animals to which we shall advert, are almost entirely marine. The flexible corallines, which contain the smallest portions of earthy ingredients, are but rarely seen fossil, but the stony corals

Geology. Ch. I.

and the hard echinodermata are exceedingly abundant in nearly all the secondary deposits

The following Table, from which Lamarck's ciliated polypi are excluded, will convey a good general notion of the relative proportions of recent and fossil zoophyta.

	Described British Species Recent.	Described British Species Fossil.	Recent Species described by Lamarck.
Polypi, nude	5	—	18
Celluliferous flexible	67	—	117
stony	21	26	61
Lamellated	3	30	134
Corticiferous	12	2	132
Carnose	47	25	194
	155	83	659

The proportion of British species is as 2 recent to 1 fossil.

	Recent.	Fossil.	by Lamarck.
Radiata Fistulida	11	—	41
Stellerida	19	5	76
Echinida	9	45	88
Crinoidea	1	27	3
	40	77	211

The proportion of British species is as 1 recent to 2 fossil.

It has often been thought, that the remarkable contrast in the proportions of the fossil and recent zoophytes of Britain might be explained by supposing that the ancient climate was hotter than at present; that, in fact, the former productions of our Northern Seas were of a tropical character; and this conjecture agrees with the deductions which may be drawn from similar comparisons in the other tribes of Animals. But the extreme rarity of flexible corallines is not confined to the strata of Britain, it is recognised over all Europe, and seems, at least in part, owing to their more perishable nature.

The contrast is equally striking among the radiaria; and it is especially worthy of remark, that the numerous group of crinoidea, so characteristic of the fossil races of a former World, belongs chiefly to the lower and more ancient members of the stratified rocks.

Passing over the remarkable Animals included in Lamarck's class tunicata, which appear to connect the zoophyta with the mollusca, and of which, being mostly perishable, no fossil species is yet recorded, we arrive at the class of conchifera, or bivalve molluscous Animals.

Conchifera.

Shells are the most numerous of all the organic treasures buried in the strata; a circumstance which might naturally have been expected from their durable constitution, their vast abundance in the present system of Nature, and their aquatic existence. When a lake is drained we find great quantities of shells in the silt which has filled its bed, but the remains of fishes and insects, and even of plants, are rarely met with.

British Conchifera.

	Described British Species Recent.	Described British Species Fossil.	Recent Species described by Lamarck.
Lamellibranchia.			
Plagymyona	186	396	800
Mesomyona	29	198	197
Brachiopoda.			
Equivalvia	—	4	—
Inequivalvia	5	159	15
	259	657	1012

The first thing which strikes us on comparing the catalogues of British recent and fossil bivalves, is the greater absolute number of the extinct species. The proportion is at present three to one, and when the strata shall have been as thoroughly explored as the shores, the number of our fossil conchifera will probably amount to a thousand, and be to the recent kinds as four to one.

On more minute comparison, we learn that the most remarkable discrepancy in the proportions is found in that singular tribe the brachiopoda, of which above 150 fossil species are already described, while the recent kinds do not exceed five. Perhaps these numbers on both sides will be changed by further discoveries. At least fifty species of spiriferæ, productæ, and terebratulæ remain to be described from the lower calcareous strata of England.

Gasteropoda.

We next arrive at the gasteropodous mollusca with simple univalve shells.

These we shall arrange in groups according to their places of residence.

	Described British Species Recent.	Described British Species Fossil.	Recent Species described by Lamarck.
Marine	210	398	1476
Estuary	—	21	22
Fresh water	31	23	50
Terrestrial	53	21 ?	274
	294	464	1822

Considerable difficulty is experienced in referring certain fossil shells to their respective recent analogues; and in consequence it is very probable that many of the species above, ranked as estuary and land shells, deserve a different arrangement. This is particularly the case with respect to the helices, helicinæ, and melaniæ.

According to the ordinary notion of their food, gasteropodous mollusca with shells may be ranked thus:

	British. Recent.	British. Fossil.	General. Recent.
Phytiphaga	233	263	786
Zoophaga	61	200	1036

Cephalopoda.

We are not aware that there are any fossil shells of the class of pteropodous mollusca, but the remains of the cephalopoda are inconceivably numerous, and far surpass the recent kinds in both variety and magnitude.

	British. Recent.	British. Fossil.
Cephalopoda	46	308

The fossil cephalopoda belong for the most part to genera not yet discovered in a living state.

The fossil species of vertebrated animals are comparatively very few, and some of them, especially fishes, not so perfectly characterised as to admit of much accuracy in their arrangement.

The following summary is chiefly taken from Mr. S. Woodward's Synoptical Table:

		British fossil.	
Fishes,	Fresh water. Marine	29	In various strata.
Reptiles,	Land. Aquatic	26	
Birds		6	In "diluvium" and alluvium.
Mammalia		1	In Stonesfield slate.
		28	In diluvium, alluvium, &c.

British fossil species.

Considered according to their situations of life, the British organic remains present the following results:

In the strata.

Terrestrial 113	Vegetables	90	and more.
	Shells	21 ?	Mostly very doubtful.
	Reptiles (Pterodactyli)	1	
	Mammalia	1	
Fresh water 56	Vegetables	5 or 6	
	Shells	40 ?	The genus Unio requires reconsideration.
	Fishes	11 ?	

Estuary 28	Shells	21 ?	
	Fishes		
	Reptiles (Crocodile, Emys. Trionyx).	7	
Marine 1139	Vegetables	3	or 4
	Zoophyta	83	
	Radiaria	77	
	Shells	909	
	Crustacea	30	
	Fishes	18	
	Reptiles	19	

In superficial alluvium, diluvium, &c. caves, &c.

Birds	6	species.
Mammalia	29	

European fossil species.

Such are the numerical relations resulting from a comparison of the extinct British species of Animals and plants on the one hand, with the recent organic Beings of Britain, and universal living races of the Globe on the other. These relations would doubtless have been considerably modified, had we found it possible to introduce accurately all the European species of fossils. But this task, owing to the still imperfect state of discovery on the subject, but far more to the unhappy confusion of synonyms, is at present hardly practicable. However, not wholly to neglect so important a datum, we shall take advantage of the information conveyed to us by Brongniart, Deshayes, Goldfuss, Dalman, and other writers, to compile a numerical statement of the most remarkable and ascertained European fossils, and to put them in comparison with a corresponding estimate of the existing species.

Remains of Animals.

	n the strata.	In superficial accumulations	Living estimated.
Mammalia	35	109	1100

Distribution of Organic Remains.

Number in different rocks.

The animal and vegetable fossils are very unequally distributed. For while some rocks are wholly filled with shells, others are absolutely devoid of them. Thus the forest marble and coarse upper beds of Bath oolite are composed of little else than shells, while the sandstones of a whole coal district may contain not one. This does not depend either on the absolute depth from the surface of the Earth, at which any rock may be found, nor yet upon its relative depth in the series of strata, but it is a circumstance established by experience, and of which some of the causes remain to be determined. The following Table exhibits the proportionate number of species of fossils in all the principal strata of the North of England, arranged according to their order of superposition.

	Thickness.	No. of fossil Species.	Ratio. Species.		Feet.
Chalk	505	43		to	12
Gault of Speeton / Kimmeridge clay	150	67 / 5	1	to	
Upper calc grit	60	5	1	to	12
Coralline oolite	60	125	2	to	1
Lower calc grit	80	40	1	to	2
Oxford clay	150	36	1	to	4
Kelloway rock	40	60	3	to	2
Cornbrash	5	37	7	to	1
Upper carboniferous series	200	30	1	to	6
Forest marble slate / Bath oolite	30	82	3	to	1
Lower carboniferous series	500	21	1	to	24
Lower oolite	60	91	3	to	2
Lias and marlstone	850	115	1	to	7
New red sandstone	?	none	——		
Magnesian limestone	215	30	1	to	7
Coal system	3000	100 ?	1	to	30
Mountain limestone	2500	200 ?	1	to	12
Old red sandstone	?	none	——		
Slate system	6000	20	1	to	300

Granitic rocks devoid of fossils.

It is necessary to remark, that the proportions derived from the preceding Table would apply only in a general way to the same strata in the South of England, for there the number of organic remains in the chalk is, at least, triple of that in the Table, the thickness remaining the same, while the mountain limestone is considerably less rich in fossils. Still less is such a Table to be viewed as a representative of the results of researches on the Continent, for there the red sandstone formation contains a very large suite of organic remains, both vegetable and animal, while neither have yet been found in this rock in England.

Fossil and recent species compared.

We shall now consider what are the *kinds of fossils* which are contained in these various strata: in other words, in what order of distribution the fossils are arranged in the Earth.

A great difference between the present system of Nature, and that of which the relics are preserved in the Earth, is obvious to any one who considers the relative proportions of the different classes of each. But the most decisive proof of the enormous changes which have happened in this respect is found by a minute comparison of the families, genera, and species. For except in the superficial and comparatively modern accumulations from fresh-water lakes, floods, or tides, and in the most recent of all the strata, scarcely one specimen of all the thousands of existing kinds of plants or Animals is found buried in the Earth.

The Earth contains the records of an ancient system of living Nature, which in its great outlines was calculated much like that which we now see in operation; but of which all the details were different. The ancient sea nourished Saurians, but they were not our crocodiles; fishes which are generally unlike the finny tribes of the existing era; innumerable shells planned on the same general principles, but executed to different patterns. The plants and the Animals of the ancient Continents performed the same relative functions as the vegetable and animal races of to-day, and formed part of a similar combination, but, as the circumstances of the Globe are now not the same as then, the forms and structures of its plants and its Animals are adapted to the difference.

Successive eras of fossil tribes.

But it must be obvious that to view the whole multitude of extinct Animals and vegetables as the products of one ancient era, to confound together all the various different strata which were successively the beds of the

Geology. Ch. I.

ancient seas, would be to destroy the meaning of all the monuments which Nature has preserved of the long periods and successive developements through which our Planet passed before the completion of its present beautiful arrangement. Each stratum was successively the bed of the ancient oceans or lakes, and the remains with which it is filled were the creatures then living in the waters or growing on the land. Each stratum, therefore, belongs to a particular period; it is the museum or repository in which Nature has preserved the plants and Animals of that period; and the Geologist, no longer confined to the mere comparison of recent and extinct species, finds in the Earth the proofs of many successive creations and abstractions of life, many systems of Nature; and by strict analogy and ample induction looks back through a long vista of revolutions, till the view is lost in the dimness and distance which hide the remote epoch, of which no evidence remains to show that the Earth was then inhabited by living creatures.

Terrestrial and marine fossils not usually abundant together.

The organic monuments of ancient Nature are either of marine, of fresh water, or of terrestrial origin. The corals, and by far the greater number of shells, are marine, certain strata are filled with lacustrine reliquiæ, and others with the spoils of the land.

There is in general the most remarkable and constant distinction and contrast between the rocks which are filled by marine remains, and those which enclose terrestrial productions. Calcareous strata generally are the most richly filled with the spoils of the sea, zoophytic, molluscous, and vertebrated Animals; but they rarely contain terrestrial plants. Sandstones and shales, on the other hand, are almost the exclusive repositories of terrestrial plants, but, unless they are calcareous, they more rarely contain marine exuviæ. The reason seems to be that the calcareous strata were deposited slowly and in tranquillity beneath the waters of the sea, and thus enveloped the dead and decaying animals of the ocean; while, on the other hand, the sandstones and shales were more rapidly aggregated, in water too agitated to favour the accumulation of marine reliquiæ. When we find in them few or no traces of land plants, we may perhaps presume that the currents to which they may owe their origin were marine, but when they are charged with ferns, equiseta, and other terrestrial plants, it seems evident that violent land-floods contributed to their accumulation.

Oceanic deposit of limestone.

The deposition of limestone by Chemical precipitation, would probably happen over a large portion of the bed of the sea, and be abundant in proportion to the depth of the water: hence the strata of limestone would thicken toward the centre of the oceanic basin. They would also be more condensed, and of more uniform texture, and perhaps of purer composition, in that direction; and since, from accurate observations of the habits of recent marine Animals, it appears that they do not multiply so much in the darkness of very deep waters as nearer the shore, we may conclude that fewer marine shells and corals, &c. should be found near the central points of the basins of strata.

How remarkably all these conditions agree in the limestones of the Alps, which appear to have been uplifted from very deep water, needs only to be mentioned. There, the rocks corresponding to our oolite, are vastly thicker, more dense, and incomparably poorer in shells, than the same strata toward the borders of the European basin. And if, in proceeding through France to the Alps, we stop to consider the Jura, we shall find its oolites, in respect of thickness and hardness, and quantity of shells of an intermediate character.

Littoral deposits of sandstone shale, &c.

On the other hand, sandstones and clays, being Mechanical deposits from agitated water, should of course be most abundant along the margins of the ancient sea, and at the mouths of ancient rivers, where the strongest movement of the waters happened. They are essentially littoral formations, and should be found thickest, and most numerous, and most varied in character, toward the borders of the basin, where the limestones are the thinnest. And as the forces of tides and currents, however powerful, are irregular and limited, the Mechanical aggregates which they occasion must be, and in general are, more confined and irregular than the wide Chemical deposits of the deep sea.

This supposition likewise agrees perfectly with what we observe in comparing the oolitic system of the Jura and the Alps with that of Northern France and England; for the clays and varied sandstones which diversify this system in the latter Countries, and separate it into many distinct groups, are scarcely to be traced in the Alps or the Jura.

Another case in point is furnished by the carboniferous limestone series of England. This limestone in the South of England is so little divided by Mechanical strata, that in the Mendip Hills, near Bristol, and around the Forest of Dean, it is commonly supposed to be one thick rock.

In the North of England it is much and evidently divided, and the number and thickness of the partings of shale and sandstone, and coal, increases continually Northwards, while the total thickness of the limestone beds grows less and less. At the same time the organic remains seem to become, if not more numerous, (a point as yet difficult to be determined,) certainly more varied in form.

The oolitic system of England presents us with another valuable illustration of the same doctrines.

The oolites of Somersetshire, Gloucestershire, and Lincolnshire form a long range of hills, and are only, and that not universally, divided by partings of clay and marly limestone. But as we advance into Yorkshire we find these spaces augment, and the widening intervals filled up by thick deposits of sandstone, shale, plants, and coal, which predominate so much in the section as almost to obliterate the separated, attenuated, and deteriorated limestones. These, however, are filled even more than usually with marine exuviæ.

The concretionary or oolitic structure is, perhaps, more decided and constant toward the borders of the strata. It becomes irregular, and at length fails in proportion as the limestone is mixed with earthy impurities. At the extreme Northern range of the degraded oolitic system in Sutherland this structure is nearly lost; it is irregular in the impure limestones of Yorkshire, becomes perfect in the homogeneous strata of Gloucestershire and Somersetshire, assumes more compactness in the Jura, and changes to dense limestone in the Alps.

This is exactly what, *à priori*, would be expected to happen. Amidst the turbulence and admixture of the littoral deposits, a process so similar to crystallization could happen but seldom and unequally, there would be a point at a certain distance from the shore at which the disturbance would prevent regular crystallization and yet would permit of concretion through the calcareous sediment, and still further the limestone would be more compact and subcrystalline.

Coarse conglomerates, for similar reasons, would be

most abundant toward the shores and more local than the finer sandstones and clays; which also would be most likely to contain the remains of plants, as these might be long suspended in the unsettled water, and be transported along with the finer matter.

The distinction here insisted on between *conchiferous and phytiferous rocks*, is so important, that we must, in speaking of the distribution of organic remains in the Earth, consider them apart; and while from the former we deduce the ancient condition of the sea at several epochs, the latter will furnish us with analogous data from which to reason on the state of the contemporaneous dry land.

We shall commence with the MARINE FOSSILS, and investigate the manner of their distribution under two general heads: 1st, their relation to the Chemical and Mineralogical composition of the strata; 2dly, to their relative antiquity.

Analogous fossils in similar rocks.

If the marine fossils are distributed in the rocks according to their Chemical nature, we shall find that similar rocks contain similar fossils. This is certainly the case with respect to the zoophytic animals, for these are almost confined to the calcareous strata. Corals, and various Animals of the class radiaria, abound in the transition limestone, carboniferous limestone, oolites, and chalk.

The remarkable brachiopodous bivalves, as spirifera, producta, pentamerus, terebratula, are also by far most abundant in the calcareous rocks. Gryphææ and smooth oysters are found in the argillaceous strata of the South of England, from the lias upwards to the chalk.

The organic remains of the different limestones of the oolitic formations have very remarkable general analogies. Thus the inferior oolite and the coralline oolite, the fuller's earth rock, and the cornbrash, hold very many closely analogous species. But it must be remembered that the distinctions of the oolitic system in England are in some degree local, and probably dependent on the littoral character of the deposits, and that in other parts all these subordinate strata coalesce together into one hardly divisible mass of oolitic limestone. The resemblance of fossils in these strata may, therefore, rather be the result of their nearly contemporaneous existence, than of the mere similarity of the Chemical composition of the rock.

These are the most remarkable instances of the association of certain organic forms with certain Chemical compounds; they are important data to support the opinion that, generally, fossil remains lie near the places where the Animals perished. But it is evident that these few analogies by no means establish a general law. On the contrary, when we proceed to consider in this point of view a large number of species, the resemblance between the organic contents of one limestone and those of another of considerably different age, is very slight and shadowy. And as no other strata than the limestones exhibit it in a striking degree, it is evident that some other cause than the Chemical composition of their repositories has regulated the inhumation of fossils.

Different fossils in strata of different age.

That cause is the subject of our next examination, the relative antiquity of the strata.

That a strict connection does really obtain between the age of a rock and the organic remains which it contains, is made evident by comparing a few well-ascertained facts.

The mountain limestone of the North of England contains, perhaps, 200 species of animal remains; the lias 115; and the chalk 43. Now of all the 358 species contained in the mountain limestone, lias, and chalk, respectively, there is *not one* which is found in two of these rocks. Neither of these strata contains a single fossil which is found in either of the others. Between the era of the formation of the mountain limestone, and that of the lias, the whole animal population of the sea had been entirely changed; and a similar complete renewal took place before the chalk was deposited. And in the Southern parts of England the chalk is covered by other more recent strata filled with shells and other marine Animals, entirely different from all those which lived and died before.

Identical fossils in rocks of the same age.

Further investigation has demonstrated, that conclusions thus drawn from local researches apply with considerable accuracy in other situations, even at great distances where the same strata occur. A catalogue of the corals, crinoidal remains, productæ, spiriferæ, terebratulæ, orthoceratites, and trilobites, of the mountain limestone in Yorkshire, may be employed for labelling the fossils collected from the same rock at Namur and Liege; the lias of Whitby contains many of the same ammonites, and the same Saurian skeletons as the contemporaneous beds at Lyme, and in Westphalia and Wirtemberg; and the remarkable echini and belemnites of the English chalk accompany that rock through France and Poland to the shores of the Baltic.

The same observations have been made on the other conchiferous strata of England. Each has been traced through the Island, and its organic treasures have been explored at every point, and in this manner satisfactory proof has been collected, that along its whole course the fossils which it contains are almost entirely the same. The researches of foreign Geologists have demonstrated the truth of this law for the greater portion of the European basin of strata. The figures and descriptions of the English fossils are referred to by the Geologists of France, Swisserland, and Germany, and no doubt remains that each extended stratum is the repository of the Animals inhabiting the sea at a certain period in the Earth's formation, exactly as the earthy bed of the present sea now envelopes the remains of its present corals, shells, echini, and fishes.

General principle of Smith.

The general principle, therefore, which regulates the distribution of organic remains in the Earth may be thus expressed. They are associated according to the periods at which they existed; and they are enclosed in the rocks which were at those times deposited by the water. And as in ancient times, much more than at present, the animal remains over considerable breadths of the bed of the Northern Sea were nearly identical, *strata of the same age contain generally the same fossils.*

Also because the inhabitants of the ocean were, in the course of time, completely changed, the old races having been extinguished, and new ones brought forward to occupy their places, *strata of different ages contain generally different fossils.*

These important propositions form the groundwork of the history of the stratified rocks, and must be ever present in the mind of the modern Geologist. The honour of their discovery belongs to Mr. William Smith, an engineer of eminence, who, being employed in 1790, and the following years, in surveying collieries, and planning and executing a canal in Somersetshire,

Geology. Ch. I.

established the English system of Geology upon the following propositions.

"That the strata are laid upon one another in a certain definite order of succession or superposition, may be traced in continuity on the surface of the Earth, and may be discriminated when of different ages, and identified when of the same age, by their imbedded organic contents."

Gradual changes in the races of organic being.

By comparing a sufficient number of fossils from all the several strata with analogous living tribes, we discover that those fossils which more nearly resemble the living kinds belong to the strata which were deposited at the least ancient period; as for example, the crag shells of Norfolk and Suffolk, the London-clay shells of Hampshire and Highgate, which are all more recent than the chalk.

In these situations we find the families, genera, and even species of shells so similar to recent kinds existing somewhere or other in the Ocean, that though they are often very different from the productions of our neighbouring seas, we not the less perceive that they belong to a system very like that now established.

On the other hand, those fossils which present the least resemblance to their successors in the modern system of Nature, belong to the older, and especially the oldest of all the conchiferous strata. It is in the transition and carboniferous limestones that the singular brachiópodous bivalves, producta, spirifera, pentamerus, the remarkable genus orthocera, the zigzag ammonites, the still unexplained tribes of trilobites, the beautiful crinoidea, chain corals, and favosites, compose a zoological suite, altogether unlike what now exists, a strange and antique order of beings adapted to the primeval deep.

If we estimate the relative periods which intervened between the deposition of any given rocks by the variety and thickness of marine strata which separate them, we shall find that in proportion to the distance of the strata from each other, in proportion to the difference of their ages, is the difference of their zoological contents. Thus the fossils of the mountain limestone are more different from those of the lias than from those of the magnesian limestone. The lias fossils are wholly different from those in the chalk, but partially similar to those in the Bath oolites.

M. Deshayes' results.

The principle that the difference of the forms of ancient organic life from those of existing nature is directly proportionate to the difference of the epochs of their existence, has been put to a severe and curious test by one of the best conchologists of France, M. Deshayes. Passing over the primary and secondary rocks, in which no plant or animal has yet been found identical with a living species, he analyzes the tertiary fossils according to their relative antiquity, and obtains the remarkable result, that the lowest and oldest of the tertiary strata contain three and a quarter per cent. of species identical with living types; that a second and less ancient group of these strata holds eighteen per cent. of such analogues; a third more recent group forty-nine per cent.; and the most recent of all these deposits contains little else than modern species. When we recollect that all these strata are of a date probably anterior to the creation of man and the present races of quadrupeds, the results of M. Deshayes' investigation must be considered as highly valuable data towards forming a just notion of the great antiquity of the stratified rocks, the long periods passed through in their production, and in the accompanying changes of organic life, the gradual nature of these changes, and the correspondence of the *General System* of Nature at all epochs, even amidst the greatest particular diversity.

Characteristic fossils.

Some fossils appear to have been in existence only during the deposit of one particular stratum, as for example, certain productæ, spiriferæ, trilobites, in the mountain limestone; axinus obscurus, in the magnesian limestone; ammonites Bucklandi, gryphæa incurva, in the lias; ammonites calloviensis in the Kelloway rock; hamites of many kinds in the Gault; ananchytes, spatangi, belemnites mucronatus, in the chalk; rostellaria macroptera in the London clay; fusus contrarius in the crag. These are said to be *characteristic fossils* of the strata, and, in general, very great importance is justly attached to their recognition; but no Geologist should permit himself to trust to them exclusively, for they are not *always and invariably* present, and he may be often called upon to fix the date of a rock by the help of other witnesses. Many fossils are found in more than one rock, and the number of these will probably be much increased by further inquiry. Thus in the South of England, plagiostoma giganteum occurs in the lias and inferior oolite, terebratula intermedia belongs to the great oolite and cornbrash, pecten lens is found in the cornbrash, Kelloway, and coralline oolite, astacus rostratus and spatangus ovalis range through the Kelloway rock, calcareous grit and coralline oolite of Yorkshire; and mya literata appears in nearly the whole range of conchiferous strata from the marlstone to the coralline oolite inclusive.

These facts entirely overthrow the notion favoured by some Geologists that each rock contains the relics of a distinct creation of animals. They prove, on the contrary, that the changes were not sudden but gradual; and suggest the hope that hereafter, when the laws of the *distribution and transference* of the *existing marine races* shall be better understood, and the history of the fossil species more complete, the phenomenon may be satisfactorily explained in accordance with the recognised laws of Nature, " constant in her ceaseless change."

Gradations of deposits and of fossils coincident.

It is generally observed that where the series of strata is complete, they are softened as it were one into another by an admixture or alternation of ingredients. Thus, for instance, in Somersetshire, the new red marl and lower lias clays are sometimes softened into one another; and in Yorkshire, the Kelloway rock, Oxford clay, lower calcareous grit, coralline oolite, upper calcareous grit, and Kimmeridge clay are so blended at their junctions as to render it difficult to draw any hard line of separation. In such cases it commonly happens that several fossils of the lower rock are continued into the next above, and thus the zoological change is as gradual as the mineralogical one. On the contrary, when two strata are separated by a hard and decided line, as, for instance, the coralline oolite and Kimmeridge clay near Oxford, we shall generally be justified in suspecting that the lower stratum is imperfect, in consequence of the removal of its upper beds before the next stratum covered it. In this case the zoological contrast between the two rocks is as decided as the mineralogical one, and keeping in view the Linnæan adage, *Natura non facit saltus*, we should be on the look out for some intermediate beds in other places. Such are described near Weymouth, by Sedgwick; and in Yorkshire, have been named the upper calcareous grit.

The chalk in England contrasts so entirely with the tertiary formations above, that we naturally expect to find in some other Country beds of intermediate character to connect them. These are found at Maestricht, where a sub-cretaceous, granular rock, intermediate in

composition between chalk and calcaire grossier, contains many fossils of the chalk, and several which strongly resemble those of the tertiary group.

The researches of Sedgwick and Murchison in the Eastern Alps, have brought to light the remarkable Gosau beds, which, by these Geologists, are thought to be of the same intermediate era.

Probably more complete researches on this point will make known a greater number of such intermediate strata, soften the contrasts between contiguous rocks, and fill up all the blanks in the harmonious system of gradually changing marine deposits, characterised by corresponding transformations of marine exuviæ.

Terrestrial animals and plants.

The remains of Terrestrial Animals embosomed in the Earth are very few, and those of plants bear so inconsiderable a proportion to the Flora of the present age of the World, as to give us much less information concerning the ancient state of the land, than the marine exuviæ afford of the former condition of the sea.

But as far as they go they confirm in the most satisfactory manner the conclusions drawn from the consideration of marine remains, of the succession of systems of organic nature. The plants which sometimes alternate with, and which overlie in immense variety and abundance the mountain limestone, are a group eminently distinguishable from those which belong to the oolitic coal beds. In the former deposit, lepidodendra, sigillariæ, stigmariæ; in the latter, cycadeæ and zamiæ; and the plants of the strata above the chalk are still of a different type.

It would thus appear that the same systems of calcareous rocks which contain the most remarkably different suites of zoological remains, likewise enclose in the alternating beds of sandstone and shale plants equally distinct.

As amongst the marine, so amongst the terrestrial remains, those most decidedly unlike the modern productions of Nature belong to the most ancient deposits. In the intermediate portion of strata the discrepance diminishes, and in the most recent rocks, the plants strongly assimilate to the genera and even species which now cover the surface.

We might here examine the conditions of the land and sea as to climate during the several epochs of organic existence, a subject of the greatest curiosity and interest, and for which an immense mass of materials is already collected; but this investigation requires the statement of details which cannot be here with propriety introduced. We must, therefore, postpone the discussion till we come to treat of the strata and their contents in the order of their successive deposition.

We shall then also enter into the history of the fresh-water formations which locally diversify the great mass of marine deposits, and contribute to elucidate the character of the ancient land and streams.

CHAPTER II.

DESCRIPTION OF THE SERIES OF AQUEOUS DEPOSITS WITH THEIR IMBEDDED ORGANIC REMAINS.

Series of Aqueous Deposits.

General basis of Plutonic rocks.

Having now stated general principles, useful alike to the Geologist who investigates in the field, and to the student who reads in his closet, we proceed to describe the successive systems of aqueous deposits, beginning with the lowest of all, *viz.* those which rest upon granite and other crystallized and unstratified rocks. That there is such a basis of crystallized rocks beneath all the strata, in all Countries, cutting off and limiting our observations, and hiding whatever wonders are concealed below, is now universally admitted. The subjacent position of granite is so fully established by observation, that even when portions of it are clearly seen to be laid upon stratified rocks, no doubt is entertained of its having been in every case ejected from its true source below all the strata. But the same observations, which so clearly establish this important law, as certainly overthrow the dogma, once held incontrovertible, that granite is always the oldest of known rocks. They prove to a certainty that granite is of all ages, or, more properly speaking, that its production has really no relation of age to the deposition of any particular set of aqueous strata; but that it has been produced by agencies entirely independent of them, and only locally, and in one sense accidentally, brought into juxta-position with them. This interesting discovery, from which we learn that the production of granite below the stratified rocks has been continued, perhaps without intermission, during the whole period of the accumulation of the strata, has greatly changed and improved our conceptions of the whole system of Geology, and is probably destined to clear still more the horizon of this Science. But we must be careful not to be allured by this new light too far from those inferences concerning the age of granite which it so properly qualifies. It does not follow, because some granite is more recent than chalk, that therefore all granite is more recent than gneiss and mica slate. It does not follow, because when in contact with granite veins gneiss may sometimes assume perhaps more than even its usual granitoid aspect, that therefore granite is merely fused gneiss, that gneiss and slate are incipient granite, and that common sandstone may in time become gneiss.

But it does follow, as a matter of high probability, independent of further observation, that because granite has been formed at several periods during the deposition of strata, by agencies excited far beneath and independent of them; and because, in some instances fragments, and universally the disintegrated ingredients of granite, lie in the oldest strata, that the production of this rock was in progress before any of the strata were deposited; whether those strata now rest upon that old granite or have been forced by subsequent convulsions into contact with newer portions of the same kind of rock.

Whatever theory on the original formation of granite we choose to adopt, it must be allowed that the igneous action to which it owes its birth preceded the aqueous, which accumulated the lowest strata now observable.

Primary strata

This being admitted, two points of inquiry suggest themselves with respect to the age of the strata which have been called primary. First, are those strata really

Geology. Ch. II.

the altered deposits of one long period of aqueous action prior to all the secondary and tertiary strata, or have many repetitions of igneous action *primarized*, to use Mr. Conybeare's remarkable expression, strata of all ages, secondary and tertiary, which happened to be the lowest at the points of action? Secondly, may we believe, as the title of primary seems to imply, that these are the oldest of all the strata, the first that were laid by water upon the consolidated igneous crust of the Globe? That these questions should be put at all will probably appear very surprising to those who have drawn all their notions on the subject from books of some date, without attending to the rapid progress of geological opinions.

not to be known only by mineral characters,

On the first question we may remark, that it must be allowed that subterranean heat, operating chiefly by the ejection of melted Plutonic rocks, has transformed to a certain degree and limited extent, strata of all ages which were exposed to this action, and thus made the lias shale of Savoy, for example, approximate to the character of clay slate. In such cases, there can be no objection, we conceive, on the part of any Geologist to apply the same term to this *change* of the rock, which we may think fit to employ when treating of the analogous *change* presumed upon very good grounds to have affected in more ancient times the strata called primary. We may, therefore, adopt at once Mr. Lyell's term of *metamorphic*, and designate by it all those parts of certain aqueous strata which have been transformed in structure or appearance by subterranean heat applied since their deposition. All strata then may become metamorphic under given conditions, and may assume, locally, some of those appearances which belong, perhaps universally, to the primary strata; but are we, therefore, to deny the antiquity of these latter? or to group all such metamorphic strata together as of indefinite age, and merely characterised by proximity to igneous rocks? Surely nothing could be more in contradiction with the principle of classification of strata, the relative antiquity of their deposition. We cannot, therefore, agree to the term *hypogene* of Mr. Lyell as applied both to granite and the strata usually called primary. When applied to granite it is synonymous with, and may perhaps be preferred to Plutonic; when applied to stratified rocks its meaning is better conveyed by the term metamorphic, which we shall apply to those portions of all strata, without regard to their age, which are in the altered condition implied.

but by their position.

The true conclusion on the subject of the first inquiry then appears to be, that we are not to assume strata to be of the primary age merely because they appear to have undergone certain changes, analogous to those which gneiss or clay slate have sustained; but we must determine their age by the very same methods as we use in any other case of stratified rocks, *viz.* by examination of their position relatively to other strata, their organic remains, and their original mineral composition and structure. Examined in this way, there can be no doubt, we conceive, that the use of the term primary as applied to the gneiss, mica slate, and clay slate systems generally, defining them as a certain mass of strata anterior to the secondary and tertiary rocks, is perfectly correct, because in all Countries where these rocks occur together, the inferiority of their position is well proved; and they have those general analogies of original composition, and those relations to organic remains, which would be satisfactory evidence in every other case. Those who reject the term primary, and yet retain the use of secondary and tertiary, have constructed a series wanting its first term.

Geology. Ch. II.

Are primary strata the earliest deposits from water?

The answer to the second inquiry cannot, perhaps, in the present state of knowledge on the subject, be given with the confidence of assured impartiality. It certainly does not follow that because gneiss, for example, is generally allowed to be the lowest of the stratified groups which we can trace, that there may not be other strata of a totally different nature below it, partially or wholly concealed by Plutonic rocks, still less is it evident that such strata may not have existed, and been subsequently absorbed into the general mass of igneous rocks below. Geologists of eminence appear to think that granite itself is a derivative igneous, from an earlier stratified rock; and that as gneiss is certainly in some respects to be compared to partially fused sandsone, so it may be supposed that while, above, the mass of strata was augmented by additions from water, it was diminished, below, by the transforming action of heat.

Strange as this notion may appear we certainly are not at present in possession of facts sufficient to wholly disprove it. But neither are there any facts to raise it above the rank of a general speculation grounded on particular and local alterations of stratified rocks. It cannot, therefore, be admitted for want of sufficient evidence, and, perhaps, the following considerations will justify us in rejecting it. Many of the primary strata undoubtedly are derived from the disintegration of preexistent granitic rocks. The character of the organic remains in these strata is in general so remarkably contrasted with those which at present exist, that, joined to the diminution and final extinction of their numbers as we descend in the series, and the almost perfect identity of their characters over immense geographical areas, we seem really to behold in them the first terms of organization, the earliest records of the establishment of life upon the consolidated crust which overspread the fused matter within the Globe.

Conclusions admitted.

However, without plunging further into premature speculations of this nature, we shall content ourselves with the admitted conclusions.

1. That there is a sequence of age to be traced through all the stratified rocks, which may, therefore, be very justly grouped in any suitable number of successive divisions, as primary, secondary, and tertiary, and that these terms, if convenient, are not improper.

2. That the series of stratified deposits, whether we know their first terms or not, were laid upon a general basis or floor of Plutonic rocks.

3. That the term primitive, whether applied to igneous or to aqueous deposits, must be abandoned, as affirming what is not, and perhaps cannot be proved.

4. The alteration of strata by general igneous agency, or by the local contact of melted rocks, being an effect wholly independent, both as to cause and period, of the deposition of strata, must be treated in connection with the other effects of subterranean heat.

Governed by these considerations, the succeeding part of the Treatise will form two clearly marked divisions: 1st, the description of the products and operations of water through all geological periods to the present time; and 2d, a similar account of the products and operations of heat.

Exceptions to this rule will occasionally occur where it is necessary to notice the changes produced by igne-

Geology. Ch. II.

ous agency in the condition of the bed of the sea, and other circumstances which influenced the character and extent of the aqueous deposits.

In the following description of strata, we shall retain the general titles of Primary, Secondary, and Tertiary Strata, and divide them into several SYSTEMS according to certain properties, or in agreement with their elective associations. The reasons which have determined the mode of arrangement in each case will appear in the history of the several systems.

PRIMARY STRATA.

System of Gneiss and Mica Schist.

These strata, derived probably from decomposed granitic rocks, with several subordinate and associated strata, all devoid of organic remains, constitute, according to the concurring testimony of geological observers, the lowest group of the whole series of Neptunian deposits. From the effects of heat upon these rocks, their natural analogy to granite is sometimes so much heightened, as to cause some uncertainty in distinguishing between them. The rocks of this whole series might without impropriety be termed *granitoid strata.* They are usually called primary, sometimes primitive strata. We use the former term in the same sense nearly as that in which M. Omalius d'Halloy employs the title primordial, and intend that it shall be understood to include the following system.

System of Argillaceous Slate.

In this argillaceous series, which includes the whole mass of the slate rocks of England and Wales, lie the most ancient organic remains yet discovered. The calcareous slates of Caermarthenshire, the black limestones of Norway, the shelly limestones of Shropshire, Dudley, and the Eyfel, belong to this division, which is generally known by the term of transition strata; a title which is found convenient, but considered by many modern writers too theoretical to be often employed with propriety. We shall chiefly employ it to designate the limestones of this period.

SECONDARY STRATA

as they occur in Europe. It is probable that other modes of arrangement will be found necessary for other regions.

System of Carboniferous Strata.

Containing a very large series of sandstones, limestones, shales, coal, and ironstone, with abundance of marine exuviæ in the calcareous portions, and a profusion of terrestrial plants in connection with the coal. The lower part of the system consists principally of red sandstone, the middle of limestone, the upper of coal shales and sandstones. The limestone has been long known in England by the name of mountain limestone.

System of Saliferous Strata.

We have chosen this title, because rock salt is exclusively found in these strata in England, and is especially abundant therein throughout Europe. This remarkable mineral is, however, found, though not in Britain, in several other parts of the series of secondary strata.

Red and white sandstones with red, white, and blue clays, gypsum and rock salt, constitute the mass of this system; and locally enclose two principal calcareous rocks, the lower one usually charged with carbonate of magnesia, the upper one a shelly limestone not known to occur in England.

Geology. Ch. II.

System of Oolitic Strata.

Consisting in England of several distinct groups of calcareous rocks, alternating with clays and sandstones which are often calcareous, the whole remarkably rich in marine exuviæ, with local interpolations of terrestrial plants and coal deposits, and one estuary formation.

The lowest limestone group is usually argillaceous, the others are mostly nearly pure carbonate of lime, and very generally oolitic. On the Continent many of the minute distinctions of these rocks disappear.

System of Cretaceous Strata.

Chalk with argillaceous marls and layers of nodular flint, form the most remarkable part of this system, and it graduates below to green, grey, and ferruginous sands, with layers of nodular schist, rich in organic remains.

TERTIARY STRATA.

These form, properly speaking, only one great and various system of sands, clays, and coarse limestones, stored with great numbers of marine exuviæ always very analogous to, and in the most recent group identical with existing species, locally interstratified with freshwater deposits of marls, limestones, and gypsum.

Above all these systems of strata lies a variety of tumultuary deposits apparently produced by violent action of moving water during and subsequent to the elevation of the tertiary strata, and enclosing in abundance the remains of extinct quadrupeds. These are termed *Diluvial Deposits.*

Lastly, we have the products of modern rivers, lakes, and tides, or generally, the deposits, whether chemical or mechanical, which have been effected by water acting *as* it now acts, and *where* it has acted, since the last great revolutions by which the relative level of land and sea has been changed. These are called *Alluvial Deposits.*

Range of the Primary Strata.

Study of mountains.

At all periods in the history of Geology, persons of enlarged views have passed over the limited areas of particular Islands and Kingdoms and have sought to connect the results of their local inquiries with those drawn from similar researches elsewhere. In this point of view the long chains and insulated groups of mountains become of the highest interest. These lofty peaks on which the snow rests for ever, whose rocks contain no vestiges of life, may be imagined to have stood up in ancient times above the level of the waters, dividing the primeval deep into seas very different from those which now branch off from the Ocean. And though this supposition is probably inaccurate, though modern researches render it extremely credible, that in fact the mountain ranges, far from limiting the ancient sea, and altering the nature of its deposits, were really raised out of its depths at periods comparatively recent, this does not diminish their geological importance. For if by means of this uplifting we are made acquainted with some of the materials which would otherwise have been concealed from the eye of Philosophy, these mountain ranges must be studied as the basis of the whole system of Geology.

They form, so to speak, the skeleton of the Earth, and are the marking features of its topography; their insulated groups characterise Kingdoms, their long connected chains divide the races of mankind, and define the geographical limits of the distribution of land animals. To the Geologist they have become still more interesting in consequence of a remarkable general law of their physical structure. For in all climates of the Earth, under every conceivable variation of external circumstances, the principal ranges of mountains are everywhere composed of similar rocks, and those originally the lowest, and in part at least the oldest, with which we are acquainted. By what violence from below they have been uplifted to their present heights, so as to break through and rise from beneath the strata which were superimposed upon them in succession, is a capital question in Geology.

These rocks are the primary strata of gneiss, mica schist, slate, and their many associated strata, the deposits of water, resting upon and often pierced by granite and other crystallized compounds from fusion. An outline of the mountain groups and chains which diversify the face of our Planet, seems, therefore, the best foundation for a systematic view of the strata which rest against these rocky barriers.

Relations of mountain ranges and groups.

It has long been the fashion to attempt to establish certain geometrical relations among the chains of mountains, to refer them to particular parallels and predominant directions, but this labour, unconnected with Geological researches, seems to have been very fruitless. Perhaps it would be more correct to say the essence of the geographical relations amongst mountains is irregularity. For though we speak of long-continued chains and belts of mountains, it is very certain, in fact, that to be assembled in groups is the real character of mountain association, and that the chains and belts are nothing but approximated groups. A Geological Map is in this respect a most valuable instructor; from it we see that, instead of the plains being insulated among the mountains, instead of the upper strata appearing in small contracted patches like oases in a desert, they spread wide, and flow round the bases of the mountains, as the Ocean encircles the islands and continents. Among the few general remarks on this subject we may observe, that the most insulated and many of the loftiest eminences on the surface of the Earth are the volcanic summits; the most connected ranges of uniformly high ground are formed by the secondary limestones. Finally, that the general outline of Countries is much influenced by the direction of their interior mountains.

European basin.

The Scandinavian chain, commencing at the North Cape, runs parallel to the coast of Norway, and gives off branches to the East which pass round the Gulf of Bothnia. The line of the Scandinavian chain may be imagined to cross the sea to Zetland, and from thence to proceed by the Hebridian Isles and the North-Western half of Scotland to Ireland, where it is much broken into separate groups in the North, South-East, and South-West of the island. The Isle of Man, the South-Western part of Scotland, the Cumbrian group, the broken mountains of Wales, and those of Devon and Cornwall, are so many separate protuberances of the exterior rocks of the Earth, which, with Bretagne and the North of Spain, compose the interrupted Western border of Europe.

The Pyrenees, ranging to the East, may be considered as carrying on, the primary range toward the Alps, which hold so long a course from the shores of the Mediterranean in a winding direction to the Danube, and seem to prolong themselves in the inferior ridges of the Carpathians toward the Black Sea and the Caucasus. If, now, we consider Caucasus as continuing the Alpine line round the Caspian Sea to the lofty Paropamisan and Gaur mountains, and from thence turn Northward along the summit of drainage including the Sea of Azof, we come to the Uralian chain, which leads us to Nova Zembla, and thus we find nearly all Europe, and a considerable tract in Asia, enclosed within this irregular circle of primary mountain groups; and it may often hereafter be convenient to speak of this space as the European Basin. It is within this region that the greatest variety of stratification has been observed.

Within this area are the primary elevations of the centre of France, the Ardennes, the Vosges, the Black Forest, the Thuringerwald, the Hartz, and the Bohemian Circle; South of it are the Sierras of the Spanish peninsula, Corsica, Sardinia, the Apennines, the Dalmatian ridges, and the mountains of Greece and Mount Hæmus.

The mountains of Africa are long, unconnected ranges. Atlas borders the Northern shore, a range parallel to the Equator determines the course of the Niger, and, perhaps, the prolongation of it defines the drainage of the Nile. The high land about the Cape runs in various directions.

Asiatic basins.

Another basin of about equal extent, but more perfectly defined in its boundaries, and more uniform in its interior composition, is that great Siberian tract which lies to the East of the Uralian, and to the North of the Altaian, Yablonoy, Stanovoy, and Kamschatdale mountains. The vast Empire of China and Tartary lying to the South of the Siberian basin, and to the North of the Indian Empires, may be considered as a third great but divided basin between the Himala and Altaian heights.

The peninsular Indian regions, with their islands stretching toward New Holland, Persia, Arabia, derive their features from considerable primary mountains directed more parallel to the circles of longitude; the Southern part of Africa is similarly defined by the long ridges of mountains which run from Cape Guardafui in the East, and above the sources of the Congo on the West, to converge about the Cape of Good Hope; while the greatest breadth of this peninsulated continent, from Cape Verde to Cape Guardafui, is coincident with the high mountains of Kong, Donga, and Southern Abyssinia, and the North-Western projection is caused by the elevated Atlas.

Principal line of mountains.

The interrupted system of primary mountains which extends from the Pyrenees to Behring's Straits may be supposed to continue in the long and magnificent Cordillera parallel to the whole Western coasts of America, while the North-Eastern shore is parallel to the Alleghany and its Northern connections, and between these and the Western Cordillera, the vast basin of the Mississippi pours its waters into the Gulf of Mexico. The Eastern projections of the coast of South America, which is in a certain degree correspondent to that of Africa, are owing to lateral extensions from the great Western Cordillera.

Though the above enumeration and classification of mountains be extremely imperfect and subject to many objections, it answers the purpose intended, which was to show that the leading features of our continents, their geographical extent and connections, are dependent on

the lines of mountainous land, and as these are constituted of the lowest and oldest stratified resting on granitic rocks, it generally happens, as Mitchell foresaw, that in every Country the secondary strata are arranged with reference to the lines of mountains.

Elie de Beaumont's Theory.

An entirely new kind of interest has lately been given to this subject in consequence of the researches of an eminent foreign Geologist. Elie de Beaumont, from considerations of some observed accordances between the direction of mountain chains and the geological era of their uplifting, has advanced the hypothesis that these two circumstances are always mutually dependent; and, in consequence, supposes that all ranges of mountains which were uplifted at the same period are parallel to one and the same great circle on the sphere. This is not the place to examine this curious question as fully as it deserves, and we shall, therefore, only mention some of the cases in which this ingenious Geologist supposes that the truth of his doctrine may be recognised.

If a great circle be conceived to pass round the Earth through Natchez and the mouth of the Persian Gulf, and the directions of mountain chains be compared with it, it will appear that the Pyrenees, part of the Apennines, the Dalmatian and Croatian ranges, and part of the Carpathians, are parallel to it. Now in accordance with some researches of Geologists, M. de Beaumont supposes that all these mountain-chains were thrown up at the same geological epoch. Nearly parallel to the same circle are the Alleghanies of North America, the Gauts of India, and the Paropamisan heights; but further information must be acquired before we can be asked to admit that these mountains may have been thrown up at the same epoch.

Another circle may be traced on the sphere parallel to the Alps, from the Valais to Styria, and to this system we may refer the Atlas, the Caucasus, the Balkan, the Himala, &c.; and, according to the hypothesis of M. de Beaumont, these must have been all raised at so late a period as since the deposit of the tertiary strata. This subject will again attract our attention.

Gneiss and Mica Schist System.

Principal rocks of the gneiss and mica schist system.

This consists principally of the two following rocks:

Gneiss, a rock composed of the same mineral ingredients as granite, but laminated and stratified;

Mica schist, composed generally of quartz and mica, in alternate layers.

With these are associated, and often intermixed,

Quartz rock, generally appearing like a semi-crystalline or imperfectly granular mass of quartz, variously modified by small interspersed quantities of mica, felspar, &c., sometimes more compact, and resembling the quartz of veins, in other examples mixed with clay slate.

Crystallized limestone mostly granular.

Serpentine, a magnesian rock generally distinguishable by its softness, smoothness, and bright mottled colours.

Steatite, a still softer and smoother rock than serpentine, generally of whiter colour.

Potstone, a soft, often grey or greenish magnesian rock.

Hornblende schist, a laminated rock of hornblende, variously modified by felspar, mica, and chlorite, generally in alternate laminæ.

Chlorite schist, a rock almost precisely similar to mica schist, with the exception of the difference between chlorite and mica. It is subject to the same contortions as mica schist, and passes like it by insensible gradations to gneiss and clay slate.

Talc schist, mentioned by M'Culloch, is another of the fissile rocks which differ from mica schist only by the substitution of one mineral for another. It is rare.

With respect to the order in which they succeed one another, nothing very definite can be advanced. The greater number of observations concur in assigning to gneiss the lowest place in the system, a conclusion supported by its evident analogy to granite, and in the same general way we may, perhaps, place quartz rock and chlorite schist in the upper part of this system, and next to the clay slate, with which, indeed, they are often associated. Limestone and serpentine are so irregular and peculiar in their occurrence, that though, perhaps, their era is more definite than that of any other of these rocks, they can scarcely be employed to mark a geological date. In some district or other nearly all these ancient rocks alternate with one another so variously and unequally, that what would be called the oldest rock in one region may be the youngest in another, and, therefore, it is no wonder if the attempts which have been made to divide the gneiss and mica schist system into several distinct formations, have wholly failed. It is not till zoological evidence is brought to bear on the subject that we are able to demonstrate completely the relative age of strata, by distinguishing different deposits and different ages of the same kind of rock.

Gneiss. Its origin.

That the materials of the mechanically aggregated gneiss rocks, of the whole series of strata, in fact, except the calcareous rocks, are derived from the disintegration of more ancient granite and other crystallized compounds, is an opinion which is strongly impressed upon every Geologist while examining the composition of gneiss.

The ingredients of gneiss and granite are the same, quartz, felspar, and mica; they are mixed with the like accidents and permutations, and occasional admixture of other minerals, and are subject in both to the same extreme variation of size. But these rocks differ in the most essential point of view under which they can be compared, *viz.* the mode of arrangement among their constituent masses. The ingredients of granite are so connected together by contemporaneous, or nearly contemporaneous crystallization, that one substance penetrates and is united into another, and we are compelled to conclude that they were accumulated together not in distinct pieces ready formed, but that they actually never had a separate existence as solids until their different properties were developed by crystallization from a fused mass.

On the contrary, gneiss well characterised shows evidently, by some degree of wearing of the edges and angles of the quartz and felspar, and much more decidedly by the laminar arrangement of the mica, and consequent minute stratification of the rock, that its materials, ready made and crystallized, were brought together and arranged by some mechanical agent, principally influenced by gravitation, in fact by water. Could any doubt remain on this subject after a sufficient examination of gneiss strata, in all their gradations from a rock resembling granite to a fine grained fissile mass, hardly distinguishable from clay slate, it would be at once removed by comparing them with a suite of sandstones, many of which, like gneiss, are composed of granitic debris and strongly allied to it in structure, but most evidently aggregated by water.

In a great majority of instances, gneiss rocks immediately follow granite; being then composed of the materials of that rock which had suffered the least degree

of waste and abrasion, it is no wonder that on several occasions it should strongly resemble its parent. And if we allow, what may probably be true, that the heat of the granitic nucleus was then sufficient in some places materially to affect the consolidation of the strata on the bed of the sea, we shall perceive another cause why the most ancient mechanical strata approach in character to the Plutonic rocks.

Though the disintegrated *materials* of granite compose almost universally the substance of gneiss, *fragments* of granite are most rarely discovered in it. This circumstance, combined with its numerous laminæ and crystalline aspect, seems to indicate that the aggregation of gneiss happened without any great degree of turbulence or lateral motion in the water. It may, perhaps, lead us to suppose that in those early periods the fluctuating temperature of the bed of the sea contributed sometimes to accelerate the aqueous decomposition of the granite, and afterwards at intervals to harden its stratified materials into gneiss.

Stratification of gneiss.

Gneiss beds are of extremely various thickness, and the laminæ of which they consist are subject to such extraordinary curvatures, that it is often very difficult to trace them.

Where other rocks alternate with gneiss, as hornblende slate or mica slate, the stratification is rendered very evident, but otherwise the beds are less regular, and are often discontinuous, as in micaceous sandstones and in argillaceous slates.

The contortions of the laminæ of gneiss are observed to be most numerous and surprising, where, as frequently happens, veins of granite, quartz, or felspar divide this rock. These veins cross the laminæ at various angles, and generally cause some peculiar twists along their sides; they not unfrequently insinuate themselves between the laminæ, and in this case, when thick and extensive, may be mistaken for alternating strata. It is probable that many cases of supposed alternation between gneiss and granite may be thus explained, and that in other cases the rock called granite may be really a coarsely granular gneiss, whose particles have been very little moved by water, or unusually affected by subsequent application of heat.

Minerals.

Gneiss being one of the most extensive stratified rocks is a rich repository of minerals, both in the New and the Old World. Garnets frequently, zircon, beryl, disthene, epidote, tourmaline, rutile, oxide of tin, oxide of iron, sulphuret of molybdena, more rarely, are disseminated in its laminæ. The veins of quartz, calcareous spar, carbonate of iron, and sulphate of barytes, which divide it, contain the sulphurets of lead, copper, and zinc, native silver, tin, &c. (*Brazil*, Humboldt,) and many other minerals occur in the calcareous strata which alternate with or are enveloped by the strata of gneiss.

Rocks associated with gneiss.

Gneiss alternates with granite in the Reisengebirge and in Quito, and in some cases graduates into the character of granite, as on the Southern declivity of the Titlis and Jungfrau; (Humboldt;) more frequently it exchanges beds with mica schist, hornblende schist, and granular limestone and clay slate. These rocks are sometimes in such small quantity as merely to mark lines of division in the mass of gneiss, but at other times they swell out to great thickness. The limestone beds in particular are remarkably local and irregular in their occurrence, and instead of extending, like the more recent calcareous strata, through large tracts of country, appear in the form of large lenticular masses, enveloped on every side by the predominant rocks of gneiss. The term *subordinate*, on a great scale, is not improperly applied to these lenticular rocks, though in local Geology, their occasional great extent and comparative regularity may entitle them to be classed under an independent title. Thus Charpentier arranges the granular limestone of the Pyrenees.

By the substitution of hornblende for mica, gneiss gradually changes to hornblende schist; the loss of its felspar approximates it to mica schist, the diminution of its mica produces the resemblance of quartz rock. A finely granular state, with more evidence than usually appears of watery friction among the particles, almost transforms gneiss to sandstone; a more minute admixture of its ingredients, with a predominance of chlorite, gives it the aspect of argillaceous slate. In all these cases great caution is required, and its geological relations should always be consulted before deciding on the name of this Protean rock. These gradations happen most frequently at the junctions and alternations of the several rocks.

Mica schist. Its origin.

Mica schist, like gneiss, appears to have derived its ingredients from the destruction of granitic rocks; but it generally contains but little felspar. May we conjecture that this mineral, which is easily acted on by ordinary agents, was itself decomposed during the disintegration of the granite, and mostly dissolved, leaving the quartz and the mica to be arranged by the water in the alternate layers which render this rock so remarkable?

The lamination of this rock is subject to much unevenness, in consequence of the irregular size and arrangement of the pieces of quartz, and the undulations thus occasioned on the micaceous surfaces, are often further modified by interspersed garnets. Besides this minute inequality, the laminæ of mica slate are liable to the same contortions and curvatures as those of gneiss; the same difficulty often occurs in tracing its beds, similar and very numerous veins of quartz traverse and mingle with its layers, and when in contact with granite it is locally penetrated by similar granite veins.

Minerals.

Various minerals are similarly disseminated through it, as garnet, emerald, beryl, disthene, tourmaline, felspar, epidote, hornblende, columbium, molybdena, rutile, oxide of tin, wolfram, oxide of iron, grey cobalt, native gold. Its metallic veins are of the same nature as those in gneiss; it alternates in the same way with quartz rock and the other slates, and encloses similar deposits of limestones. It seems, therefore, almost superfluous to say, that the line of rigid distinction between the mica schist and gneiss can only be drawn in the closet. Yet, in fact, on a great scale the two rocks retain their typical characters over large tracts of country, and must be considered apart.

Quartz rock.

Quartz rock, in the greater number of instances, seems a more recent deposit than mica schist and gneiss, though indeed, by an easy change of its composition, it becomes nearly identical with them. This circumstance, combined with the internal evidence of texture, seems to decide the question of the origin of quartz rock, and to prove that, however altered by subsequent igneous action, it is originally a Neptunian and mechanical deposit. The degree of compactness which it exhibits varies through a large range, in some cases approaching the loose granular character of sandstone, in others the density of the quartz of veins. In this latter case it seems that the mass is composed of fragments so firmly

united as to suggest the idea of their having been fused together since their deposition from water. Perhaps, also, in some cases, what has been considered as quartz rock may be really an expanded or overlying vein.

Minerals.

In South America this rock is the repository of many rich ores and metals. Native gold is found in Brazil in a stratified rock of quartz, and micaceous iron ore, which is suspected by M. Eschwege to be the original repository of diamonds, and appears to be intimately related to quartz rock. The flexible quartz of the same country is a granular rock with drusy cavities containing topaz and amethyst. (Brongniart.)

Crystalline limestone. Its origin.

Crystalline limestone is in general observed to be stratified, frequently to alternate with gneiss and mica schist, and is therefore a Neptunian deposit. Its frequent high state of granular or saccharoid crystallization may perhaps be due to changes operated since its deposition, and partly occasioned by the action of subterranean heat, of course more sensible in the lower than in the upper calcareous deposits.

It is difficult to imagine that such a rock could be formed by crystallization from water, often in laminæ exceedingly thin and regular, and alternating with evidently mechanical deposits. That the calcareous matter of many rocks, at first precipitated in sediment, has been since arranged in crystalline and concretionary masses, is certain. Thus the oolitic structure, thus the crystalline cement of the Lincolnshire oolites, has been occasioned. These effects, it is now known from artificial trials and from observations in Nature, are more decisive when heat and pressure operate upon the particles. By this combination, the earthy sediment of chalk is condensed into crystalline limestone.

The deposits of crystalline limestone, whether distinctly stratified or not, are in general detached and limited, and so entirely enveloped in the strata of gneiss and mica slate, as to compose but a subordinate member of those extended formations. This fact appears to indicate that in the earliest periods of Neptunian operations, the precipitation of calcareous matter was occasioned by agencies of a more local and limited nature than those which produced the broad strata of lias, oolite, and chalk.

May we imagine that the accumulation of these nucular or lenticular masses was determined by local developements of subterranean heat, which directly, by change of temperature, or by intermediate chemical agencies, might render the calcareous matter insoluble? However we may seek to explain it, the fact is undoubted, that during the aggregation of the gneiss and mica slate systems, a large quantity of calcareous sediment was deposited, not in one uniformly extended stratum, but at scattered points, and in unequal quantity. And this irregularity of deposition continues to be observed in an inferior degree in the limestones of the clay slate system, which are often lenticular, but above this point, when the influence of the internal heat must be supposed less intense and more equally diffused, the calcareous strata become at once more abundant, more regular, and more uniformly extensive.

Minerals.

Though primary limestone be, in fact, a simple rock, its aspect admits of many variations from the unequal admixture of other mineral substances. Of these the most frequent are mica, talc, and steatite, the latter of which often communicates a green or mottled colour to the whole rock. Crystals of augite, (Tiree,) garnets, and felspar, (Col. de Bonhomme,) occur in it in some places, and tremolite and argillaceous slate lie upon its laminæ. It sometimes assumes a brecciated character, as if composed of limestone fragments, and more rarely contains fragments of rocks of the gneiss and mica slate system.

It is the fruitful source of statuary and architectural marble, contains a great variety of minerals, and is locally traversed by veins of quartz, felspar, and granite, and by veins of cobalt, galena, iron.

Contains no organic remains

The limestone associated with gneiss and mica slate is usually, perhaps always, destitute of organic remains; while part of that associated with clay slate almost invariably contains shells, trilobites, or corals. The gneiss and mica system may therefore be considered as *hypozoic*, or beneath the strata which contain reliquiæ of life; while the clay slate system is clearly *epizoic*, or within the zoological era. But this distinction, when applied to such vast thicknesses of rock devoid of these remains, and variously alternating, is rather doctrinal than practical, and being founded solely on a comparison of the calcareous strata, we shall so restrict any use which we may find it convenient to make of these terms. They are besides theoretical terms; for if we suppose the crystalline limestones devoid of organic remains, to have derived their peculiar texture from changes subsequent to their deposition, under the influence of subterraneous heat, it is possible that the absence of organic remains may be often a consequence of this change. This is possible; at the same time it must be owned, that circumstances hereafter to be mentioned concerning the limestones of the slate system above, appear strongly confirmatory of the hypothesis which these terms involve.

What observations remain to be made on the other rocks associated with grieiss and mica slate will be found in the following section.

Districts of the Gneiss and Mica Schist System.

The extent of Countries occupied by gneiss and mica schist with their associated rocks is enormous; and there are few districts of sufficient area where granite appears, without being followed by these deposits. But the order of their succession, and their relative thickness, are very uncertain. In some districts gneiss, in others mica slate, in others quartz rock, make up the whole visible system, and are immediately succeeded by clay slates. There are even cases where the whole system is wanting, and large areas of granite are immediately invested by clay slates and limestones containing organic remains. In England, for example, gneiss and mica schist, and primary limestone, and quartz rocks, are almost unknown; but in Ireland, and especially in Scotland, they are abundant, and include among them many gradations, chlorite slate, talc slate, hornblende slate, &c.

In England, &c.

In Cornwall and Wales the granitic rocks are almost universally succeeded by modifications of clay slate; and though in Cumberland the granite of the river Caldew is indeed covered by rocks, having the character of gneiss, mica schist, and dark hornblende slate, (provincially called whintin,) their area is inconsiderable, and the latter rock soon changes to clay slate. At a place called Martindale, at the Eastern foot of Caldbeck Fells, is a fine-grained variety of gneiss in very thin, straight laminæ.

Granite veins are rarely known to divide any of the

rocks of this region. Quartz rock occurs in the Lickey Hill near Bromsgrove, and gneiss and quartz rock were found by Mr. Horner bordering the granite of the Malvern Hills.

The general order of succession among the primary strata in Scotland may be represented in a diagram as in pl. i. fig. 12, but it must be remembered that all the terms of the series are seldom coexistent in the same vicinity.

Gneiss in Scotland.

Gneiss is abundant in Scotland, particularly in the Northern and Western parts, and being exceedingly variable in composition, is very often undistinguishable from mica schist, under which head apparently M. Boué has preferred to class many of its varieties.

Gneiss constitutes almost the whole mass of Iona, Tiree, Coll, Rona, and the Hebrides, and enters largely into the composition of the Zetland Isles, which are in some measure to be viewed as a prolongation of the Hebridian group, as the Orkneys appear to be an extension of the Eastern rocks of Caithness. Housa, Burra, Whalsay, Out Skerries, and Yell, and the Western parts of Fetlar and Unst, and part of the Mainland of Zetland, are gneiss. The remainder of the Mainland is principally mica slate, and the two rocks are partially separated from each other by an interrupted deposit of limestone. The gneiss is often porphyritic, as in Unst; at Hagrasattervoe (Hibbert, *Edin. Phil. Jour.* vol. ii.) it appears to contain masses of granite as well as to be traversed by veins of sienite and talcose granite. Kaolin is derived from it in the Mainland and in Fetlar. Gneiss exists likewise in the Orkneys around the granite of Stromness. (Boué.)

In the Hebrides this rock changes often from the typical mixture of quartz, felspar, and mica, by the substitution of talcose minerals and hornblende for mica, by the omission of the quartz, and by the interlamination of argillaceous schist. Some varieties are extremely slaty, and suffer rapid decomposition; others approach nearer to granite, and present rude and naked surfaces and precipitous faces, with few brooks and little alluvium. The direction of the strata in the Hebrides is North-East and South-West, but the declination is obscured by frequent contortions, which in Macculloch's opinion are most frequent in the vicinity of the granitic veins which divide all the gneiss rocks, except those which are associated with clay slate; and the drawing which he presents of the contorted laminæ of gneiss and hornblende slate, in connection with ramifying granite veins, near Cape Wrath, seems to justify his views. The laminæ of gneiss are often peculiarly bent, or apparently dislocated along the line of the veins; and sometimes masses of this rock are curiously enveloped in their substance.

The veins are not often filled with granite of the ordinary kind, but with a compound rock, in which felspar highly predominates, so as to form in several places (Harris, South Uist, Rona, and Coll) a real graphic granite, which in Coll contains garnets. Veins of quartz, occasionally metalliferous, likewise traverse the gneiss of Coll and Tiree. Garnet, rose quartz, zircon, hornblende, epidote, fluor spar, iron pyrites, and sulphuret of molybdena, occur in the gneiss.

Mica schist is not abundant in the Hebrides, but in Rona, Coll, and Tiree, it alternates universally with the gneiss.

Gneiss occurs in many places, as round the granitic mountains of Bræmar and Lachin y gair, at Kincardine in Ross-shire, and other points in the extreme North of Scotland; but the most abundant and interesting deposit adjoins to the granite of strontian.

It forms the beautiful and picturesque region around Loch Sunart, which strongly resembles the Trosachs of Loch Katrine, being equally rich in wood, and remarkable for intricate confusion of rugged surface.

The curvatures to which its laminæ are here subject are very numerous and extraordinary, veins of quartz, felspar, and granite are extremely common, garnets abound in it at certain points, and the metalliferous veins with carbonate of strontian, harmotome and remarkable calcareous spar are highly interesting. On the Eastern side it is bounded by porphyritic masses, but in other directions appears to be overlaid by mica schist, to which its composition approximates.

Mica schist in Scotland.

But the principal part of the Highlands is occupied by the mica schist formation, whose strata, ranging with more or less regularity North-East and South-West, notwithstanding the interruption to their continuity by the unstratified rocks of the Bræmar mountains, and the groups of Ben Cruachan and Ben Nevis.

The South-Eastern limit of this vast deposit is the line of the foot of the Grampians from the Forth of Clyde to Stonehaven. Deposits of red sandstone, lias and a carboniferous part of the oolites border the Eastern coast from the River Spey to Duncansby head, and extend through the Orkneys; rocks of igneous origin, associated with the preceding, mostly occupy St. Kilda, Skye, Rum, Eigg, Mull, parts of Ardnamurchan and Morvern. Within these limits, and with the exception of irregular masses of igneous rocks and of gneiss, the whole of the vast space belongs to the mica slate system, with its included quartz rocks, limestones, serpentines, potstones, its associated hornblende and talcose slates, and its overlying clay slates.

The mountains of this system of rocks are formed into little groups separated by deep valleys and long lakes, and their bases being usually and thickly covered with birch, underwood, and sometimes with forests of oak, while their summits rise often more than 3000 feet above the lakes, the beauty of the scenery is admirable. Scenes, indeed, of an alpine character are very rare in Scotland, and, perhaps, nowhere occur except in the Cuchullin mountains of Skye and the granite peaks of Arran; but very grand and imposing effects are produced by the combination of narrow woody defiles, precipitous slopes, and rocky crested summits. The general outline of the mountains is pyramidal, but this form, elegant at a distance, is broken on a near survey by fantastic projections, and bare cliffs, and by numerous channels, which after storms are changed into a multitude of waterfalls. The valleys destitute of lakes are usually wild and barren, and covered with scattered rocks.

Several of the most remarkable valleys in the Highlands follow the ranges of the strata, as for example, the extraordinary valley of lakes which are united by the Caledonian Canal whose highest summit is but 90 feet above the sea, the valley of the Spey, *Glen Tilt*, Loch Tay, Loch Long, Loch Fyne, Loch Awe. M. Boué observes, that the longitudinal valleys are remarkably narrow as if mere slits in the country, while the numerous transverse valleys are in general more widely expanded.

One of the most interesting valleys in Scotland is Glen Roy, rendered classical by Macculloch's description

Geology. Ch. II.

in the *Geological Transactions*. Two narrow, parallel, contiguous terraces, perfectly level and continuous along the whole length of the glen, mark the higher part of its bordering slopes with a singular and most surprising character, the effect of ancient local operations of level water; most probably an included lake, whose lofty barrier at first subsided a little, and then gave way altogether. It has been with less probability conjectured that these lines are the traces of the ancient margin of the sea, left uninjured during a subsequent elevation of the whole country to the extent, perhaps, of 1000 feet. By the natives of these wild regions they have been traditionally supposed to be the works of man in the fabulous Ages.

As might be expected, the forms of the mountains, and especially the shape of their summits, is considerably characteristic of the kind of rock which constitutes them. Compare, for instance, the irregular head and broken slopes of the Cobler and other mountains of mica slate, with the smoother sides and less angulated chloritic top of Ben Lomond, and the conical summits of quartz on Benan, Schehallion, and the Paps of Jura.

Neither are the features of the valleys and waterfalls independent of the nature of the rocks which they traverse. The unequal hardness of mica slate, in particular, is often evident in the rapid streams, by singular hollows and pits in their course, and deep cavities under the cascades. A waterfall near Loch Earn Head exhibits this feature very remarkably.

The most important point of view under which mica slate can be considered mineralogically, is the well-known variation and entire change of character to which it is subjected by alteration in the proportions and permutation in the nature of its ingredients. It cannot be thought surprising that a rock, constituted probably of the débris of many granitic aggregates, should be extremely various in its composition. M. Boué is of opinion, that we may observe on a great scale these variations to be dependent on the general principle, that in proportion to its antiquity or proximity to granite, mica schist becomes more felspathic and more quartzose, in fact, more like gneiss; and on the contrary, that in proportion as it recedes from the fundamental rocks, it becomes more talcose, more chloritic, more argillaceous, in fact, more like clay slate.

Examples of gneiss-like mica slate are found in Glen Tilt, Dalnacardoch, and many other points of the Blair Athol Country, near Tyndrum, and sparingly around the granite mountains of Arran.

In some specimens (Glen Roy) it appears composed of little else than mica folded and twisted round garnet crystals, in other cases (Ben Nevis) the garnets form almost distinct layers. In some cases (Glen Roy) the white mica and quartz form very smooth and attenuated laminæ, in others (Trosachs, Loch Earn) the quartz is in thick irregular plates, which mark one of the gradations to quartz rock.

Quartz rock in Scotland.

Quartz rocks and quartzose mica slates are seen, in the North of Scotland, in Moidart, along Loch Shiel and Loch Eil, and the Eastern side of Loch Linnhe. Above the granite of Glen Tilt, quartz rocks abound in Ben y gloë, and several mountains round the granite of Braemar, and may be well studied in the valley of the Bruar near Blair. They reappear in Mount Alexander and on the sides of Loch Rannoch, constitute the pyramidal summit of Schehallion, and on the borders of the granitic desert of Rannoch Heath are traversed by granitic and porphyritic veins. Further West the Island of Jura is distinguished by the obtusely conical quartzose mountains called the Paps of Jura, and the same rocks extend into Isla. Dr. Hibbert has described the quartz rocks in Zetland.

Talcose slates in Scotland.

Talcose and chloritic slates, holding an intermediate mineralogical character between clay slates and mica schists, also for the most part occupy the intermediate geological position. They may be well studied on the banks of Loch Lomond and Loch Fyne, and several points on the South slope of the Grampians, where they are often rich in quartz, and remarkable for minute undulations and greater contortions. Chlorite slate is also found in the Long Island, and in Fetlar and Unst. The mica schist of the Highlands very generally contains garnets, which are of various size and occur under different circumstances. It seems difficult to explain the very common association of garnets with mica schist and gneiss, except by admitting that this mineral is one of the effects of heat applied to those rocks since their deposition.

Hornblende slate in Scotland.

Hornblende rocks, especially hornblende slate, occur in various combinations with mica slate. Hornblende is seen plentifully in Glen Tilt, and is much traversed by granite veins, on both sides of the Pass of Killicrankie, South of Schehallion, North of Ben More, in the upper part of Loch Lomond, and under Ben Cruachan.

Serpentine in Scotland.

Serpentine, a rock whose geological relations are very imperfectly understood, occurs in Scotland at many places; accompanied generally with talc or steatite, and diallage rock. It is said by Boué to be most frequently placed among the upper beds of talcose slate, though occurrences of serpentine, in small quantities, accompany the limestones of Iona, Glen Tilt, Harris, and Tiree. (Macculloch.) On the South side of the Grampians it occurs only at Cortachie on the North Esk, but through the North of Scotland its localities are more scattered. (Near Drimnadrochit, near Inverness.) The serpentine of Portsoy, said to be employed in some of the apartments at Versailles, forms "three vertical beds," one of them enclosed between hornblende rocks, another between hornblende rocks and primary limestone, and the third between quartzose talc slate and mica slate, which is covered by beds of limestone, hornblende slate, and talc slate, and the junction of all these rocks is softened by a mutual exchange of ingredients. In Scalpa, an irregular, highly inclined bed, one hundred yards thick, of serpentine traverses the gneiss promontory of the lighthouse, and exhibits at its boundaries against the gneiss abundance of hornblende crystals, layers of talc slate, and a sublaminated structure. It contains steatite, asbestus, &c. The granite veins here observed traverse both the gneiss and its included serpentine, and in the latter rock talc is superadded to the ingredients of the vein.

Serpentine exists also in Lewis, and occurs in Zetland in considerable abundance and beauty, both in the Mainland, in Fetlar, and at Brassa Sound in Unst, where it contains chromate of iron in sufficient abundance to be of considerable value in commerce.

Potstone is found in Glen Elg opposite to Skye, and in the serpentine of Scalpa. But the most remarkable rock of this kind is found at St. Catharine's near Inverary, on the opposite side of Loch Fyne. It is imperfectly slaty, and has been employed in the erection of the mansion of the Duke of Argyle. Boué also adds as localities, the districts of Strathearn and Breadalbane.

Geology. Ch. II.

Primary limestone in Scotland.

Primary limestone. One of the most important of the subordinate or interrupted rocks which diversify the vast surfaces of gneiss and mica slate in Scotland remains to be noticed. So much has been before said on the composition of this rock, that we shall here dwell chiefly on the question of the relative ages of the different deposits. In the absence of organic remains, we can only examine the associated rocks, and the texture of the limestone itself. The white marbles of Iona are found in a system of rocks by some referred to mica slate, but considered by Macculloch to be gneiss. The variously coloured marble of Tiree with its imbedded augite and hornblende lies in a system of alternating gneiss and mica slate. That of Glen Tilt, characterised by its accompanying tremolites, lies in a quartzose mica slate, associated with hornblende slate. Notwithstanding the want of agreement in character between the limestones, and the more important differences between the rocks which enclose them, some Geologists think these limestones are of the same age.

Boué, following up the notices of Macculloch, traces the line of the Glen Tilt limestones to the East and to the West. In the Western direction they proceed from Gow's bridge, crossing the hills at Lude, tending toward the South, passes through the Glen of Fincastle and across the valley of the Tumel. It is conjectured that limestones of the same range continue by Mount Alexander, and the base of Schehallion, from whence it proceeds through Glen Lyon to the side of Loch Tay, at the foot of Ben Lawers, reappears in Crien Larich, at the entry of Strath Fillan to the West of East Tarbet, in Knapdale, and the head of the valley of Croë.

Eastward from Glen Tilt, this limestone is traced in the course of the North Esk, and in the valley of the Dee near Bræmar, &c.

So extensive a range of limestone rocks in the direction of the strata of mica slate, seems, indeed, to require no additional evidence of its being throughout a contemporaneous deposit. The limestones on Loch Laggan and Loch Eil in Inverness, and at numerous other points in Aberdeenshire, are referred by Boué to the same era.

Second range of primary limestone.

A second range of limestones, lying chiefly in argillaceous and chloritic varieties of mica slate, is considered by the same author to be of more recent origin. The points are near Blairgowrie, at the foot of Ben Vorlich on the North side of Loch Earn, Balquhidder, Inverary, Knapdale, and Lorn, and the limestones of Balahulish, Cairndow, and Dalmally, as well as those which run from Boharm to Bamff, are classed with these more recent limestones.

Perhaps the relations between all these points may not have been correctly ascertained. In every attempt to trace a *contemporaneous line* through the older strata devoid of organic remains, much must be trusted to vague analogies; but there seems excellent reason for admitting that these calcareous rocks, like those which are more perfectly traced among the newer strata, were the produce of a few definite periods, and not mere irregular formations having no relation to each other in respect of time.

The granite of the Isle of Man is followed by very little gneiss, mica slate, and quartz rock. The mica slate is traversed by veins of quartz and schorl. (Henslow, *Geol. Trans.*)

North of Ireland.

The older strata of the North of Ireland may be considered as in part a prolongation of those of Scotland; thus the extensive formation of mica slate in Londonderry and Donegal is on the line of the chain of the Grampians, continued through Jura and Isla; and the clay slate ridges which border the Mourne mountains, run in the direction of the Mull of Galloway and the clay slate chain of the South of Scotland, while between these two systems of slates are carboniferous limestone, red sandstone, and other strata of newer origin, corresponding to those which separate the analogous chains in Scotland.

The mica slate rocks are principally of the talcose varieties without garnets, but producing hornblende. Deposits of laminated primary limestone of different colours, containing talc, quartz, hornblende, or pyrites, with veins of quartz, chlorite, and calcareous spar, occur in the mica slate, in many parts of Antrim and Londonderry. Hornblende slate likewise forms distinct beds in the mica slate of this region, and felspar porphyry is described under the same circumstances. (Berger, *Geol. Trans.*)

South of Ireland.

In the South-Eastern part of Ireland, granite is extensively seen, and mica slate forms two ranges along its Eastern and Western boundary, and wherever it occurs is in direct contact with the granite. On the Eastern side of the granite it runs in a narrow course North-East and South-West, dipping steeply South-East, and consists of alternate layers of mica and quartz of extremely variable thickness. On the Eastern brow of Rochetown Hill mica slate runs into a natural hollow of the granite, still retaining the North-East and South-West direction of its strata. On Maulin Hill it is singularly and fantastically contorted on the small scale. There is a prolongation of the body of mica slate at the head of Glenmacanass, gradually narrowed in its Western progress, and constituting a wedge-like mass, inserted into the body of the granite, and enclosing a seeming bed of granite six to ten yards in width, besides irregular masses of granite incorporated with the slate. In the same vicinity greenish, sectile, talc slate lies imbedded in the mica slate, and is used for various purposes of architecture and sculpture.

In Glenmalur occurs a remarkable instance of decided alternation of granite and mica slate under circumstances very favourable for its display. In a space of 208 fathoms no less than five distinct alternations of granitic beds, with as many layers of mica slate, are clearly traced, and several of these beds are compound, or really made up of similar alternations of granite and mica slate, or quartz and mica slate. The great mass of granite is below, and the great mass of mica slate above, constituting the hill called Lugduff. Grenatite abounds in this slate.

Similar alternations occur in other neighbouring places, making a total thickness of one-third of a mile, and the whole system ranges North-East and South-West, and dips South-East. On the North-East they probably abut, and terminate against the granite. The mica slate on the summit of Lugnaquilla is likewise interstratified with granite. Clay slate bounds *it on the* East, and at length, coming into contact with the granite cuts off its further progress to the South.

On the Western side of the granite the mica slate is still less extensive. It is found to enclose beds and elliptical masses of granite in Glenismaule; and it is mentioned that a granite vein, four to eight inches wide, ranging 25° North of West, cuts off the mass of alternating strata, without occasioning any displacement. In

the same valley are two distinct beds of compact greenstone porphyry in the mica slate, one four feet wide, the other two feet. Andalusite abounds in the mica slate of this country, and greenstones of various kinds alternate with it.

The frequency of the phenomenon of alternation between mica slate and granite is a singular feature in the Geology of this part of Ireland, for the full display of which we are indebted to Mr. Weaver. (*Geol. Trans.* vol. v.)

In Brittany.

The tract of old rocks in the North-Western part of France is one of the most extensive in Europe. The granite, generally the most elevated, is separated from the secondary strata by a system of gneiss and mica slate, and by another system, into which they pass almost indefinitely, of clay slates. In the Departments of Calvados and La Manche these two systems appear as zones around the granite, the gneiss being within the clay slate. Quartz rocks of blue colour, and pegmatites with tourmaline, are associated with them, and veins of quartz and granite traverse them. (De Caumont, *Geol. du Calvados.*)

In the Pyrenees.

The granitic masses of the narrow chain of the Pyrenees having been uplifted in much confusion, are very irregularly bordered; in several places they are overlaid by gneiss and mica slate, but generally by the clay slate series. Charpentier, a disciple of Werner, thinks the gneiss of the mountains which border the valley of Soulan, so intimately connected by gradation and alternation with the subjacent granite, as to be necessarily united therewith into one formation. In many instances gneiss and granite are described as alternating in very thin layers. In other cases, vast blocks of micaceous gneiss of 100 cubic fathoms' bulk are buried at intervals in granite, always preserving one constant relative position or direction of strata. These are thought by Charpentier to be of contemporaneous origin with the granite, which passes into them at the sides, and thus interlaminates the gneiss.

Mica slate, in the same manner, is intercalated with granite in a great many places, and quartz and felspar bands occur in the granite. In many places in the Pyrenees the "granite" contains beds of stratified granular limestone, (such as in other districts lies in the gneiss,) with graphite, talc, fluor spar, mica, hornblende, &c.

The more modern view of these phenomena is that they are quite consistent with the doctrine that granite is an igneous, but gneiss and mica slate originally aqueous rocks, and that in some cases what is called granite, is in fact gneiss with the aspect of granite, derived from a more than usual condensation and greater effect of heat. M. Boué, Dufrenoy, and other writers, have proved beyond a doubt the powerful action of heat along the Pyrenean chain, as evinced not only by the usual subcrystalline character of the clay slates, but also by the metamorphism of the chalk into the characters of primary limestone, with abundance of metallic and granitic veins at the line of junction of the altered stratified and the igneous rock. The age of the eruption of granite along this chain is, by observations of Dufrenoy, determined to be, at least in part, posterior to the chalk.

It is extremely probable that the same kind of explanation will be found to apply equally to the alternation of granite and slates in Ireland and Cornwall, and to the alternations of porphyry and slate in Cornwall, North Wales, and Cumbria. It is to be remembered, however, that the igneous theory, as it has been termed, does not by any means require that all these beds of seeming granite should be pronounced to be altered gneiss, nor that the beds of porphyry should be considered as altered clay slate. Alternating igneous and aqueous action is perfectly intelligible, and exemplified in modern operations of Nature; but certainly in many cases, both in Cornwall and Cumbria, it appears the more correct view to suppose a gradual and partial *rearrangement* of the materials of the rock, through the long action of heat. This would well agree with the indefinite boundaries of the porphyries of Cornwall and Cumbria, which often pass by insensible modifications into ordinary slate.

In central France.

The great central plateau of old rocks in France from which the Loire, Vienne, Dordogne, &c. take their source, is chiefly a granitic and porphyritic tract, surrounded by oolitic and carboniferous rocks, but clay slates and gneiss rocks appear in the valley of the Vienne, and occupies a large part of the Southern boundary. Near Limoges are alternating beds of granite and gneiss, and some subordinate beds of pegmatite and hornblende rock; the gneiss passes by one variation to granite, by another to mica slate. The ranges of the strata near Limoges are North-East and South-West, and they are crossed by decomposing elvan courses to North North-East. Tin veins occur near Vaulry in gneiss as well as in granite. Towards the borders of the district the gneiss becomes less granitic, more associated with hornblende slate, and encloses deposits of micaceous limestone. Serpentine lies in this gneiss in many places, and M. Cordier appears disposed to refer them all to one contemporaneous, though interrupted deposit. The pegmatites and kaolins, which have resulted from them by decomposition, of St. Yrieux, form numerous veins and strings in the gneiss and hornblende slates, which sometimes intercalate themselves between the laminæ. Quartz rock of bluish colour exists likewise in the Black Mountain and elsewhere. Oxidulated iron abounds at many points in the gneiss; galena, phosphate of lead, carbonate of copper, antimony, and hematite, are the products of the veins. (Desnoyers.)

The most remarkable alterations of secondary limestones take place, according to Dufrenoy, along the line of junction with the granitic and porphyritic masses. Thus the lias and oolite become metamorphic, and are traversed by metalliferous veins, as in Cornwall and Brittany, where the slates are metalliferous principally in the same situation.

Other localities in Europe.

After these details of the circumstances attendant on gneiss and mica slate at so many interesting points, we shall only add some general observations on the range and extent of this system of rocks in other Countries. Gneiss and mica slate in small quantity occur in the Vosges, and gneiss more abundantly in the Black Forest.

The long irregular chain of the Alps contains a vast quantity of gneiss and mica slate, variously extended around the talcose granite cores of Mont Blanc and St. Gothard, from the Mediterranean almost to the Danube.

Deeply buried beneath the valley of the Danube, gneiss and mica slate do not reappear around the granitic origin of the Carpathians. Their place is supplied in this chain by a vast deposit of clay slate.

The primary mountains which encircle Bohemia are

on all the Southern half granite. Gneiss and mica slate are superadded on the West, and the former rock in particular abounds in the Erzgebirge. The Riesengebirge granite is bordered on the North by gneiss, on the South and East by mica slate, and these rocks are associated with granite in the range which divides the drainage of the Oder and the Elbe.

These rocks are most extensively spread over the Northern parts of Europe, from Copenhagen round the Gulf of Bothnia, along the Uralian chain toward the Caspian Sea and the Caucasus.

In America.

In America, Humboldt describes gneiss as less abundant along the high chains of the Andes than along the inferior mountains of Caracas, in Oronoko, Brazil, New Spain. It is occasionally auriferous, and contains micaceous, primary limestone. The most considerable masses of mica slate mentioned by this distinguished traveller are those of the Cordillera of the shore of Venezuela. This formation in the Andes is less rare in the North than in the South of the Equator. No where, perhaps, is the total suppression of mica slate formations more frequent than in the Cordilleras of Mexico and South America.

The Eastern primary range of North America passes through the United States from the St. Lawrence to the Mississippi in a direction nearly parallel to the coast, and generally 100 miles distant from it.

Gneiss is the most extensive of the primary strata in the Northern States of America, filling large tracts in New Hampshire, Massachusetts, Connecticut, the Highlands of New York, Pennsylvania, Virginia, &c. and the Southern Counties. It retains in general its place next to the granite, and is often succeeded by hornblende rock. It contains deposits of primary limestone, "calcareous sandstone," and in several places, laminated plumbago, adularia, zircon, magnetic iron ore.

It is traversed by veins of granite in Haddam, full of beryl, schorl, and other minerals.

Mica slate is less extensively spread, and occupies a narrower course in Massachusetts, Connecticut, the Highlands.

Talcose slates succeed, and granular limestone appears in ranges above it in Connecticut, Pennsylvania, and Maryland. It is often magnesian or dolomitic in Massachusetts and Connecticut.

Quartz rock occurs in the Western part of Massachusetts.

Slate System.

Inversely proportional to the gneiss and mica schist.

It may be taken as a general rule that the two systems of rocks which compose the primary strata are inversely proportional to each other. Countries which abound with gneiss and mica schist are indeed seldom quite devoid of clay slate; but they also seldom contain it in great quantity. On the contrary, where clay slate is extremely abundant, gneiss and mica slate are less extensively developed. This is at least very much the case in the primary mountains which surround and diversify the basin of Europe.

In Scotland the Grampian ranges, and, in fact, all the Northern primary strata of that Kingdom, are principally composed of mica schist and gneiss, while clay slates prevail almost exclusively in the Southern chain of the Lammermuir and Galloway ranges. As before observed, the mica slate system in Ireland is distinct from the clay slate tract. The Cumbrian granitic rocks are surrounded by clay slates in great plenty and variety, but there is little gneiss or mica slate. The same is observed in the large primary tracts of Wales, Devon, and Cornwall, and it is a characteristic feature in the Geology of the Harz.

Cumbrian slate district.

For the purpose of clearly unfolding the relations of the various argillaceous, calcareous, and conglomerate rocks which compose the vast and variable mass of the clay slate system, it is desirable to fix our attention upon some district where the variety of the rocks is considerable, and the order of succession is perfectly known. Such is the district which overlooks the Northern English lakes. We shall, therefore, describe it as a type of the clay slate system, and refer to it as a constant term of comparison.

The granite of Skiddaw is covered by gneiss and hornblende slates. The latter rock gradually changes to the chiastolite slate and other argillaceous slate of Skiddaw. The argillaceous slates here commencing form a series of three members, distinguished by their mineralogical characters, and a constant order of succession. See pl. i. fig. 13.

Dark lowest slates.

The lowest slate rocks of the system range to the South-West from Skiddaw and Saddleback by Grisdale Pike to Dent Hill, filling the valleys of Derwentwater and Crummock water. South-West of Buttermere, they are concealed by the elevated ranges of High Steel and Red Pike, but reappear in the lower parts of Ennerdale, and abut against the limestone border near Egremont.

The slate of this district is generally of a dark bluish colour, and of very uniform texture, soft, fine-grained, and very fissile, and has been employed in the vicinity of Keswick and Hesket Newmarket for roofing houses; but for this use it is not very suitable, for it easily perishes in the atmosphere. In consequence of its want of durability, the mountains of this slate have smoother contours, more uniform slopes, and a more verdant surface than those of the following series.

In one point on the South-Western edge of Derwentwater we have observed an undulated variety of this slate of paler colour and more shining surfaces, indicating an approach to the nature of chlorite slate. Chiastolite is imbedded in the lower part of the rock in Skiddaw and Bowscale Fell. Where this slate shows itself by the sides of the lakes, its laminæ appear to be generally vertical, and often flexuous. Veins of quartz are frequently seen penetrating and interlaminating its masses. In several places they yield abundance of lead ore; and in the district called Newlands, abundance of carbonate of copper, and some cobalt. Mr. Otley states that the lead veins run North and South, and those of copper East and West. Steatite is found in Borrowdale, and mixed with the slate in Martindale. Two salt-springs have been detected in it near the upper end of Derwentwater.

Green middle slates.

These rocks, sloping to the South-East and North-West from Skiddaw and Saddleback, are covered by the middle system of slates. These are best developed on the South-Eastern slopes, and occupy a long range of mountains parallel to the Skiddaw slates, in those highly picturesque and romantic valleys wherein the lakes of Ulswater, Haweswater, Thirlmere, and Wastwater, spread their beautiful waters.

The lowest rock belonging to this system is a red, argillaceous, fissile stratum, abundant in the Eastern shores of Derwentwater, especially about Barrow and in St John's Vale, in both localities resting upon the Skiddaw slate.

Geology. Ch. II.

Red rock.

It is a very singular rock, characterised universally by its mottled colours, and apparently heterogeneous composition. Its first aspect reminds us of an old red sandstone conglomerate, but on closer inspection the seeming certainty of its brecciated character vanishes; the seeming fragments of which it is composed appear to be scarcely more than colour spots, and we leave the rock very undecided as to its origin. In some cases, however, it must be owned, the appearances of aggregation are very difficult to withstand. It is distinctly stratified, with dip to the South-East, and is of considerable thickness. Its pervading tints vary from bright red to purple, and in proceeding up Borrowdale, rocks succeed in the same geological position, at first blue, and afterwards greenish, while the seeming conglomerate aspect becomes less distinct, the spotting is smaller, the hardness greater, the rock splits vertically, and becomes, in fact, a coarse green slate. Amidst the numerous varieties which succeed, we perceive about the Bowder stone some remarkable laminated beds, with talcose surfaces, and variegated with nodular concretions of calcareous spar, green earth, and differently coloured quartz or calcedony, having altogether very much the aspect of amygdaloid. This peculiar slate, which seems to indicate the united agency of water and great heat, dips in the same direction as the red rock of Barrow, and thus helps to prove that in this tract the vertical cleavage of slate is transverse to the lines of deposition. It appears to harden and change character in Wallow Crag. There are, perhaps, repetitions of this remarkable rock in other parts of the slate systems, since it occurs at the upper end of Ulswater, in Helm Crag, Loughrigg, and other points about Grasmere and Elter Water, in Ulpha, and other places. But it is possible that these may be the same beds; a conjecture supported by the fact, that red rocks, like those of Barrow, lie beneath them at Grasmere. And, indeed, in Helvellyn and other mountains we see the coarse slate rock vary through all appearances from amygdaloidal slate to fragmentary greywacke, and this again assuming more regularity, resemble clay porphyry, from which its uncrystalline felspar and recurring fragmentary structure do not always clearly distinguish it. On the other hand, we see the coarse rocks of Borrowdale and Patterdale lose their spotted aspect, become more uniformly green, more regularly fissile, and change to the fine-grained green slates of Langdale and Coniston Fells, or the pale grey rocks around Grasmere, or the "rain spot" slate of White Moss.

Greenstone rocks are variously associated with this system of slates, sometimes in the state of dykes, sometimes as overlying masses, particularly about Keswick. The sienitic rock of Red Pike, Scaleforce, and Wastdale, which seems to come up through the lower slate, ramifies its masses through and over these rocks. Red porphyry dykes divide them on Armboth Fell; large masses of red and dark porphyry with garnets, lie on their lower portions in St. John's Vale; and if the slate of High Pike belongs to this system, the felspathic (or elvan?) courses there known, may be added to more massive accumulations of igneous products which border Thirlmere Lake. The sienites and hypersthenes of Carrock Fell, and the granitic tracts of Wastdale and Devock Lake, must probably be viewed as rising upwards from below the whole series, and spreading on the surface of the strata of slate.

The minerals which this district yields are rather numerous than valuable. The veins are generally quartzose. A great variety of lead spars, sulphuret and carbonate of copper, with galena, pitchy iron ore, wolfram, &c. are found in Caldbeck Fells, among the slaty and sienitic rocks. Galena has been worked in Griedale, (Ulswater,) copper ores at Coniston and in the lower beds in Newlands, plumbago in Borrowdale, micaceous iron ore in Eskdale, &c.

In consequence of its superior hardness, and its frequent association with igneous products, the green slate mountains assume bolder forms, present more lofty and rugged peaks, and more inaccessible precipices than the softer slates of Skiddaw. For the same reason, the streams instead of furrowing the smooth slopes in straight courses are twisted about among the unyielding rocks, and broken into admirable cascades.

Dark limestone.

The region of green slate is rather indefinite toward the South-East, where it is overlaid by the uppermost series of greywacke slates. Perhaps it may be best to adopt as the conterminous line, the narrow course of dark calcareous slate ("transition limestone") which passes from Long Sleddale by Low Wood Inn and Windermere Head to Coniston Water Head and Broughton Mills. This rock contains organic remains, as caryophyllia, millepora, producta, spirifera, orbicula; but generally in so imperfect a state of conservation that their specific characters are very obscure. The calcareous layers alternate with layers of slate of the same colour, and are with difficulty distinguished from them. Their dip is usually very rapid.

Upper slates.

Above this regular band of limestone lies a thick series of rocks, containing several varieties, all capable of being ranked as greywacke. The lower rocks, very dark in colour, are frequently quarried for slate, (Broughton, Ulverstone, &c.) occasionally for flagstones and tombstones, (near Hawkestone, crooks of lune, &c.) which are sometimes parallel to the stratification. (Otley, *Guide to the Lakes.*) In the long aberrant range of slate rocks beneath Ingleborough and Penygant, (*Geol. Trans.*) dark slate of similar aspect reappears in Clapham Dale and between Ribblesdale, and furnishes enormous tables of slate with nodules sometimes formed round lituites, in the nearly vertical partings or cleavage. At Ingleton the greenish slate seems rather referable to the middle slate system.

Above the dark uniform slates previously described lies a system of more micaceous and more granular rocks, which extend to the South-Eastern border of the primary district. They are of two kinds: 1. fissile with micaceous partings parallel to the stratification, sometimes reddish, and appearing to resemble certain laminated red sandstones. 2. Granular, not fissile, with disseminated mica. These varieties may be observed frequently alternating in the country North of Kendal and about Kirby Lonsdale, and present the most striking analogies to arenaceous freestone and micaceous flagstone. In the upper part of this system (near Kendal and near Kirby Lonsdale) lie layers of shells, or rather casts and impressions of shells of the following genera: orthoceras, patella, trigonia, plagiostoma, pecten, gryphæa, turritella, melania, spirifera, terebratula. (*Geol. Trans.*)

Cleavage of slate.

A very remarkable feature in the region of this upper slate series, is derived from the uncommonly crystalline aspect of the rock on a large scale. The numerous joints intersecting one another at acute angles, and ranging with admirable precision for a hundred yards or

 more, divide the faces of the hills into long ridges of smooth, rhomboidal rocks, alternating with parallel heathy or grassy hollows. This is probably the reason of the peculiarly rough and knotted appearance of many hills of this tract. It is difficult to resist the belief that this is owing to a real crystallization, and that slate is a crystalline rock with definite angles and regular cleavage. But on pursuing the inquiry it will be found that the parallelism of external joints and internal cleavage is a phenomenon of a different kind from geometrical crystallization, not produced in consequence of an original equilibrium amongst the particles, but from symmetrical consolidation of the mass, exactly as the cuboidal blocks of oolite, the rhombs of shale, and prisms of basalt have been formed.

Among the common appearances of cleavage is that represented in pl. i. fig. xiv. where different layers (strata) of slate are cleavable at different angles of incidence.

Scotland. It will be difficult to put the slates of Scotland in comparison with those of Cumberland, as they are deficient in limestone. In general terms it may be said, that the dark pyritous slates of Argyleshire and the West of Scotland seem analogous to those of the lower Cumberland group; but those which constitute the Lammermuir and Dumfriesshire mountains have the characters of the greywacke system.

Ireland. Mr. Weaver describes the slate which borders the granitic tracts South of Dublin, as alternating with greenstone and greenstone porphyry, and enclosing clay slate conglomerates.

In Windmill Hill, Mr. Weaver describes several alternations of a granular felspathic rock with the clay slate. And in the mountain of Croghan Kinshela, in the space of 630 fathoms, are eight principal beds of alternating granite and clay slate, besides several of granite and clay slate mixed, and four of clay slate and greenstone.

Clay slate and quartz rock are likewise seen in frequent alternation on the Eastern coast of Ireland, and thus remind us of the similar rocks in Anglesea. No organic remains have been found in these tracts; but Mr. Weaver describes the occurrence of fossil plants perfectly analogous to those of the carboniferous rocks in coal seams of the South of Ireland, supposed to be included in the greywacke slates.

Isle of Man. In the Isle of Man, Mr. Henslow is inclined to consider in one instance the cleavage and stratification coincident. Elvan dykes and granite veins divide it.

Wales. In Wales, according to Professor Sedgwick and others, the slate system between the old red sandstone and the granite presents the following general characters in a descending order.

1. Greywacke containing, in a state of considerable developement, several divisions, calcareous, arenaceous, and shaly, with organic remains, in considerable numbers and variety. (Buallt, Llandilo.) The layers of the upper part of this rock conduct us by an easy transition into old red sandstone.

2. The great slate formation, containing in all its parts indications of mechanical origin. Detached deposits of limestone.

3. A vast group, differing from the ordinary character of the Welsh mountains, in containing a very large proportion of felspathose rocks of porphyritic structure. Of this the mountains of Snowdonia are probably the lowest portion; they contain organic remains.

4. A group of slaty rocks described by Henslow in Anglesea, consisting of chlorite and mica slates, and quartz rock.

Nearly all that is valuable in the Geology of the slate system of Wales is due to Henslow's description of Anglesea, Sedgwick's labours in Snowdonia, and all its intricate dependences, and Murchison's recent and detailed investigation of the South-East portion of the district from Shrewsbury to the mouth of the Towy. The results of this friendly partition of labours have been eminently successful; while in the North-Western district the general inferiority of position of the chloritic and micaceous schists to the whole clay slate system of Wales is clearly proved; the true place of the Snowdonian shells fixed in the very lowest portion of the clay slate; the extent and effects of subterranean convulsion and intrusion of igneous rocks, very fully pointed out: these phenomena have been linked by discoveries on the other side of the region into a complete system of slaty deposits. The greywacke series on the South-East border, described by Mr. Murchison, fortunately presents a series of phenomena, deficient or not clearly separated in the slate district of Cumbria,—a vast number of organic remains, lying in distinct groups, a series of distinct members of the greywacke, which these fossils appear to characterise, limestones of different ages which clear up the difficulty, always felt hitherto in fixing the true relations of the limestones of Dudley and Llandilo; and, finally, ancient Plutonic operations accompanied by elevations and alterations of the strata. We may now, upon sufficient data, affirm that the Welsh and Cumbrian series of slates presents a nearly complete record of all the principal deposits, with their characteristic organic remains from the gneiss and mica schist upwards to the carboniferous system; and, as these slates graduate below into the mica schist system, and above into the old red sandstone, to show a continuity of marine operations in a part of the geological scale of periods where formerly was an utter blank. Mr. Murchison finds the greywacke series divisible into six groups, in the following descending order, all ranging North-East and South-West.

Groups in the upper slates of Wales. The first group, below the old red sandstone, is a series of thin-bedded arenaceo-calcareous strata, 1000 feet thick, abundant in the neighbourhood of Ludlow, and stored with brachiopodous bivalves of the genera terebratula, strophomena, leptæna, and orthoceras; and trilobites of the genera homonolotus and calymene.

The second group is limestone 100 feet thick, in its upper part interlaminated with the superior beds, and below resting on shale. It is identical with the celebrated limestone of Dudley, contains nearly all its well-known fossils, and ranges in a continuous escarpment for many miles North-East and South-West, but grows thinner continually to the South-West, so that in the prolongation of the strata parallel to the South Wales coal fields this interesting rock is nearly extinct.

The third group is the dye earth of Shropshire, which was once supposed to overlie the Dudley limestone. It is, perhaps, 2000 feet thick, and is made up of incoherent, greyish, argillaceous, sometimes micaceous schist. The higher strata are in some places charged with many orthocerata, lituites, asaphus caudatus, &c Other beds are locally distinguished by concretions of argillaceous limestone formed around corals and other

organic bodies; and toward the base of this deposit a thin, calcareous zone is observed in Shropshire, containing the pentamerus lævis, *Sow.* and a new species of that bivalve.

The fourth group is an arenaceous sandstone series of various colours, chiefly red and blue; calcareous bands are associated with the sandy strata, almost made up of productæ, leptænæ, and spiriferæ, with crinoidal remains, all of species peculiar to this group. Thickness 1500 or 1800 feet.

The fifth group consists principally of black shale enclosing beds of greywacke, flagstone, or calcareous slate, which, prolonged to the South-West, join themselves to the trilobite beds of black limestone and calcareous flagstone at Llandilo, and thus establish the distinctive relations of that rock to the Dudley limestone. The thickness of this group probably exceeds that of any of those mentioned above.

The sixth group is a vast deposit several thousand feet in thickness, consisting of red, coarse, quartzose conglomerates, schistose beds, and purple-coloured sandstone. No organic remains have been yet observed in this group.

Below all these comes the great slate formation with detached masses of limestone, also ranging North-East and South-West, as about Bala lake.

Charnwood Forest.

In Charnwood Forest the sienitic rocks are followed by clay slates of different kinds, compact and coarse, soft and silicious, green or dark coloured.

Cornwall and Devon.

In Cornwall and Devon the order is,

1. Greywacke, with calcareous slaty beds sometimes containing organic remains, and detached deposits of limestone.

2. In two places a serpentine formation, which, in the Lizard, contains diallage rock, talc slate, hornblende slate, and mica slate, appear to occur beneath the greywacke. Its relations are obscure, but it is superior in position to the following formation.

3. The great formation of metalliferous slate (killas) with many subordinate beds of greenstone, felspathic slate, &c. It is traversed by granite veins, and is said to alternate with granite.

Dr. Boase, in his recent Work on the *Geology of Cornwall*, arranges the schistose rocks of Cornwall in two groups, the upper of which is associated with black calcareous slates, and the lower much interlaminated and mixed with porphyritic masses, eurites, quartz veins, &c. At its junction with the granite, the killas is frequently intermixed with granite veins, and is altered in some respects so as to lose in part its fissility, and to be described by the miners as "Elvanny Killas."

The general impression concerning the schistose rocks of Cornwall is that their mineral composition is a mixture of quartz, felspar, and mica; and so, probably, is that of most clays and shales.

The extensive deposit of serpentine of the Lizard is seen in several places to rest upon and alternate with greenstone and porphyry, in others to rest upon green talc or clay slate. At Coverach are rocks of various texture, in some measure intermediate between serpentine and diallage rock, which suggest important reflections on the relation of this beautiful rock; and, in the same place, the greenstone abounds with diallage, and contains likewise titaniferous oxide of iron. Veins of steatite divide the serpentine, and are thought by Sir H. Davy to be derived from decomposed felspar. Dykes of sienite, and saussuritic diallage rock pass through the serpentine.

The clay slate deposits of Brittany are said to resemble those of Cornwall. Very similar serpentine occurs there, and in addition ogygiæ, calymene, euomphali, and posidoniæ.

Two-thirds of the area of the chain of the Pyrenees is composed of clay slate, which appears to exhibit varieties of texture and aggregation like those described in the Cumbrian district, with the exception of the coarser kinds being dark green, micaceous, or granular, aluminous or silicious. Frequently these slates alternate in very thin layers with limestone, in which case a number of calcareous fibres crossing the slate, but not the limestone, give the mass the peculiar appearance of schiste rubanné; limestone abounds with this slate series, and is either compact, slaty, or granular. It contains crinoidal and zoophytic fossils, "ammonites," and a few other shells, and some are found in the alternating slates. Anthracite in small quantities is mixed with the slates, quartzose, felspathic, and greenstone rocks alternate with them. Most of the metallic products of the Pyrenees are found in the clay slate system. (Charpentier.)

Ardennes.

The Ardennes mountains, which cover so vast a tract in France, Luxemburgh, and the Rhenish Provinces, and which support the volcanic products of the Eyfel volcanos, are mostly composed of greywacke slate analogous to the upper part of the Cumbrian system. Good roofing slate is not common in this tract. Remains of ferns, like those of the coal beds, of productæ and encrinites occur in it.

Rhine valley.

Organic remains are not very rare in this formation on the banks of the Rhine. In the valley of Niederlahnstein we found the greywacke slate rich in fossils, among which spiriferæ were most numerous. The lower part of the slate series of the Rhine appears to be the most quartzose, and it will be found occasionally difficult to say whether a particular rock should be called greywacke, or quartz rock.

Harz.

The slates of the Harz contain productæ, calymene tristani, posidonia becheri, &c.

Scandinavia.

The slate system of Scandinavia presents a general analogy with that of Cumberland. In its upper part are black limestones in nodules or beds alternating with slate and containing trilobites of the genera paradoxites and agnostus, and orthoceratites.

Tarentaise.

The group of the Tarentaise, referred by MM. Brochart and De Buch to the age of transition rocks, is very dissimilar from the general character of the deposits of that period. Consisting of granular and talcose limestones, gneiss, and mica slate, it may be compared to the earlier primary rocks, while the organic remains sometimes found in it, and the coarse greywackes which belong to it, unite it to the latter period of the system. (Humboldt.) Similar remarks are applicable to the metamorphic strata of the Valorsine, and perhaps, in both cases, the peculiarity of aspect is much dependent on the local influence of heat derived from the neighbouring granitic masses and veins.

North America.

Clay slate is the lowest rock in North America containing organic remains, which are always of marine origin, and it rests immediately upon granular limestone. These remains are extremely rare: brachiopodous bivalves and orthoceratites are found at Troy. This rock may be traced over a space of two thousand square miles in the Counties of Saratoga, Schenutady, Albany,

Geology. Ch. II.

Rensselaer, and Columbia. It extends into the Western margin of Massachusetts, and there rests immediately on granular limestone. (Eaton.) Its laminæ cross the planes of deposition as in the slates of England, and all the accidents to which the European slates are subject are repeated in America. It is silicious about Hudson's. Clay slate is not extensive in South America.

Transition Limestone.

Analogous to older primary limestones

The limestones associated with clay slates are almost universally known to Geologists by the name of Transition Limestone, a term which we think liable to little objection, even by those who reject the title of Transition Strata, as applied to the whole or any considerable part of the slate system. These limestones are usually, as in Norway and Cumbria, of a very dark colour, fetid when struck, and more or less associated by alternation and gradation of characters with the slate rocks; or they are mere calcareous slate, as in some parts of South Wales; or they form considerable rocks, as in the Eifel, at Dudley, in Shropshire, and Herefordshire. There are also in North Wales and Devonshire portions of limestone more analogous in character to the primary limestone, and like that very limited in extent, appearing like huge ellipsoidal concretions wholly enveloped in slate. These latter, like primary limestone, are generally deficient in organic remains; they appear to range parallel to the original planes of stratification in the slate, and may thus eventually be found of great use in subdividing that thick system of deposits They may be considered as generally, perhaps universally, more ancient than the more connected range of limestone and calcareous slate with organic remains. It is in the upper part of the slate series in South Wales, Herefordshire, and Cumberland, that the limestones with organic remains are found.

by the manner of its accumulation.

But even the most connected portion of this upper transition limestone is liable to so great alteration of quality and variation of thickness as to present some points of analogy to the earlier calcareous deposits. From very thin and unimportant traces above the Vale of Towy, the uppermost limestone swells out to a considerable thickness in Herefordshire, Shropshire, and Dudley, and the number of organic remains varies in the same proportion. About Ludlow the thinner beds of this limestone occur principally in nodules united with much shale, both containing orthoceratites, trilobites, &c. Even amongst the thicker beds of the limestone rock, Mr. Murchison has recognised the same remarkable tendency to ellipsoidal concretions.

The transition limestone of the Hartz presents two considerable independent masses, enclosed between conformed strata of greywacke. Near Rütslau, East of the Brocken, it abounds in madrepores, which, however, are chiefly rendered visible by decomposition of the rock. This character also obtains in much of the dark limestone of Norway and of the Cumbrian lakes. The laminated limestones of South Wales and the Eifel, are of a lighter colour, and generally associated with shales and grey or reddish sandstones, such as usually belong to the top of the slate series. The fossil remains of these situations are in consequence usually well exhibited on the surface of the beds, when, either naturally or by chemical or mechanical means, these surfaces can be cleared. (M. de Bonnard, in De la Beche's *Memoirs.*)

As on the one hand the irregularity and frequently nodular character of the limestones associated with slate, present a curious analogy to the older calcareous rocks of the gneiss and mica slate system, so the upper fossiliferous limestones of the slate, have often a special resemblance to the mountain limestone of the succeeding epoch, both in mineralogical character and organic remains. Judging from specimens only, and from an imperfect view of the English and Belgian series of strata, many Continental Geologists have been unable to discriminate between our transition and carboniferous limestones. Their conclusions on this point appear to have been sometimes influenced by the fact that trilobites and orthoceratites, as well as many encrinites, occur in both these rocks. Nevertheless they are really and permanently distinct, and their organic remains belong undoubtedly for the most part to very different species, and present altogether perfectly characteristic groups.

Geology. Ch. II.

Analogous to the newer carboniferous limestone,

but distinct from both in England, &c.

No English Geologist can for a moment hesitate to distinguish the fossils of the transition limestone of Malvern and Dudley, on the one hand, from those of Derbyshire and Flintshire on the other, nor should it be found difficult to separate in like manner the transition limestone of the Eifel from the carboniferous limestone of Namur. Both it is true are contiguous to slate, nor do they occur superimposed in one section; but the Namur limestone *lies on* the greywacke of the Ardennes, that of the Eifel *is enclosed in* it, and forms really a part of the slate system, as much as the limestone of Christiania, Cumbria, and Caermarthenshire. One principal reason of the confusion among Continental writers on the subject of these calcareous deposits in England, is the almost universal deficiency of the true carboniferous limestone beneath all the coal fields of continental Europe, except those of Mons, Namur, Liege, Dusseldorf, &c.

Finally, we must repeat the remark formerly made, that all the hard lines of distinction, which for convenience we draw across the scale of strata, may be locally exact and defined, but vanish on a more extended comparison of distant localities. The limestones of the slate system, generally, appear to connect the oldest calcareous rocks of the gneiss with the comparatively modern limestones of the coal measures. The greywacke slates which enclose them are also so much changed from the type of clay slate, as to assume very nearly the aspect of sandstones and shales, frequent in the carboniferous system; and thus, both by analogy of fossils and gradation of mineralogical characters, we are led without any startling chasm from the primary to the secondary strata.

The whole series of strata one system.

Moved by these considerations, some eminent English Geologists appear disposed to unite together the carboniferous system and the transition limestone group, and in some cases this may be a very convenient mode of arrangement; but tried by general comparisons it seems to offer no special advantage. For, by the same rule, we ought certainly to form but one class of rocks from the gneiss to the new red sandstone, since it can be most clearly proved that, in all this vast series, alternations and gradations prevail; but further, we should by rigorous extension of this mode of classification, have no division at all from the gneiss to the tertiary strata. In fact, it is already certain that the *whole series* of strata is a consequence of repeated actions of the same causes under modified circumstances, and the classification of the strata must be left in a great measure to the moderation and local convenience of the cultivators of Geology.

Geology. Ch. II.

There is little doubt that the line here drawn between the slate system and the carboniferous system may be easily recognised throughout Europe; and if in some cases the upper slates assume the aspect of sandstones and shales, and even contain traces of coal and plants, such as usually occur above, and the two sets of limestones thus divided resemble one another in certain mineral characters and organic remains, this ought not to surprise us, for it is a part of the general process of Nature.

Succession of primary strata.

To these remarks we shall only add a short connected view of the sequence of limestones in the whole primary period, according to our notions of their affinity, placing them in a descending order, with their alternating strata.

In the slate system.

- a. Arenaceous, calcareous, and argillaceous strata containing organic remains.
- 1. The limestone of Dudley, Ludlow, Herefordshire, full of organic remains.
- b. Die earth of Shropshire, containing organic remains and calcareous concretions. Arenaceous strata with organic remains and calcareous bands.
- 2. Llandilo limestone, associated with black shales, both containing trilobites and other fossils.
- c. Upper greywacke slates of Westmoreland, containing orbiculæ, orthocerata, and other organic remains.
- 3. Black slaty limestone of Westmoreland, with cyathophylla, millepora, orbicula, but hitherto no trilobites. Probably the limestone of Okehampton in Devonshire, and that of Bala in North Wales.
- d. Slate rocks.
- 4. Detached limestones of North Devon and North Wales.
- e. Slate rocks, rarely containing a few shells.

- f. Chloritic and micaceous schists of the Grampians.
- 5. Crystalline limestone of Loch Earn, Inverary, Dalmally, no organic remains.
- g. Chloritic and micaceous schists. Mica schists and gneiss.
- 6. Crystallized limestone of Glen Tilt, Strathfillan, Glen Croe, no organic remains.
- h. Gneiss, mica schist, &c.

General Conclusions concerning Primary Strata.

The general system of operations disclosed to us by an examination of the primary strata, presents the following leading points.

A general basis of igneous rocks.

I. The lowest rocks which we can trace, those upon which the vast accumulations of stratified rocks rest, are such as from all their characters appear to have been produced by igneous agency. These granitic, hypersthenic, &c. rocks are crystallized like the products of fire, composed of minerals like those observed to be generated by heat, and combined in a very similar manner. They show no action of water, either chemical or mechanical, nor contain the reliquiæ of living beings. The almost universal extent of these rocks, combined with the abundance of their disintegrated materials in the older strata, proves the great extent of the igneous agency developed in the earliest eras definable by Geologists.

Influence of heat on primary strata.

The same inference of a pervading and powerful developement of heat in those early periods, may be safely drawn from a consideration of the generally high degree of solidification among the primary strata, and their frequent though imperfect crystallization. There is little doubt, or rather the Geologist of sufficient observation considers it a matter of certainty, that the crystallization of primary limestone, the conglutination of gneiss and quartz rocks, and the rhomboidal fissures of slate, are due to the same cause as the conversion of chalk into such limestone, the induration and semifusion of sandstones, and the prismatizing of shale by the action of basalt, and by the heat of a furnace; and it is certain from various facts that these characters were acquired by the primary strata before the formation of any member of the secondary rocks.

Organic remains absent from the lowest primary strata;

II. Possibly this great and continuous heat beneath the ancient beds of the Ocean, may be admitted as a reason for the paucity of animal and vegetable life during the primary epoch. The fact, however, is that among the older of the primary strata the remains of plants and animals do not occur; and it is probable that the living wonders of Nature were not then in existence. It is, indeed, maintained that such remains would be wholly destroyed in the rocks by the operation of such a heat, and this opinion may be supported by many strong analogies. But as marine organic remains do occur, though rarely, in the midst of the slate group, (Snowdon, Tintagel,) and become numerous in and near the calcareous bands of the upper portion of that series, it appears safer to admit that the heat, or some other unknown condition of this early period, was unfavourable to organic existence in the sea. It seems almost demonstrated that at this period there was very little dry land raised to the surface of the Globe; for all the present Continents were certainly uplifted at subsequent and successive epochs, and therefore land plants could not be abundant.

become frequent in the upper.

III. But in proportion as the igneous agency found vent, in the same ratio as the mountains were uplifted, we find the organic reliquiæ of the sea and of the land imbedded in greater abundance. The plants indeed imbedded in coal strata associated with the upper part of the slate series (if really belonging to this system) are local deposits, and not at all to be compared in quantity with several accumulations of later date; but this is also in exact accordance with what is known of the relative extent of land at the different epochs.

Objections to this hypothesis considered.

It may be objected by those who see in the ancient effects of Nature nothing but the result of the present measure of natural operations, that two-thirds of the Globe are now covered by water, and that the depression of one large tract may have corresponded to the elevation of a smaller, and that remains of plants and animals may occur in the submerged portion of the crust of the Earth, of higher antiquity than any of our elevated strata. This *may be true;* and it may also be true, as some persons suppose, that stratified rocks full of organic remains occur beneath the granitic floor; but as neither of these hypotheses can be proved or even examined, they must remain as *mere speculation.*

But it may also be objected that the whole force of the argument as to the non-existence of organic beings in the earliest primary periods, goes upon the supposition that the primary strata of the same kind are all respectively of the same age, which demands the admission of almost universal formations; and this can never be allowed by those who adopt the existing measure of the effects of the natural agencies employed on the Globe, as a standard for all past periods of time.

No formation now in progress has more than a very limited area and a local character; but this very fact is decisive against the doctrine of the uniform rate and constant momentum of the several agencies of Nature; for no one can consider the wide strata of the chalk and oolite, and the still more expanded saliferous rocks, without being struck by the contrast between them and what we know of the varying bed of the actual seas. But

Geology. Ch. II.

these systems of strata, extensively as they are spread over the basin of Europe, appear, when contrasted with the primary strata, mere local deposits. If all the characteristic mountain ranges of the World show themselves composed of these strata, and furnish proof of the superior antiquity of these strata to those which surround the mountain slopes; and contain, though rarely, organic remains which do not exist among superior rocks; if, in short, these latter have the characters of nearly contemporaneous and comparatively recent origin, and the others of nearly coeval ancient date; why are we to reject the plain and obvious inferences from these facts, in order to embrace a narrow speculation, which, by fettering the mind to the results of observation on divided seas, low temperatures at the surface, and diminished heat within the Earth, refuses to consider the results of operations in the wide Ocean, brought on by almost universal chemical and mechanical agencies of heat?

General ground of argument.

In maintaining the *uniform character* of the natural terraqueous agencies, and the *constancy of their mode of action*, all Philosophers are agreed; but, as in every other problem submitted to investigation, experiment, or observation, the *conditions* are to be determined before the rate and measure of Geological results can be expressed on a scale of magnitude or number. In a Science founded on observation, these conditions cannot be known beforehand, they are the very objects of which we are in quest, and our only mode of approaching them is by analyzing the effects which have been produced by the known laws of Nature, operating under these, at first unknown, conditions. What is the object of an experimental investigation, in which first the law is given, and next the conditions are assumed, the result of their combined operation having been previously defined?

Greater effects of heat in the older Epochs.

A history of the successive revolutions in the state of the Globe, must indeed be founded on a survey of the chemical, mechanical, and vital phenomena now produced by the atmosphere, rivers, the sea, and volcanos; and all conclusions concerning the intensity, duration, and extent of igneous and aqueous agencies, in past Geological periods, must proceed upon an examination and estimate of these agencies in the existing periods; but the ratio of their effects at different periods is to be determined by evidence, not assumed by conjecture.

The results of examination of the organic remains in the several strata, and of the character and condition of these strata, according to their relative antiquity, leave no doubt of the vastly greater and more general influence which, in the older Geological periods, the *proper* heat of the Earth had upon all the operations of Nature in the sea and on the land, an influence far more equable as well as more intense than that exerted by the Solar rays, independent of the Seasons, and coextensive with the Globe.

Surely, then, under these peculiar conditions, the laws of Nature which are concerned in the operation, themselves invariable, must have operated on a greater scale, and perhaps with higher intensity, than that which now characterises their effects.

All the results depending directly on the *quantity* of communicated heat,—as, for instance, most of the phenomena connected with the decomposition, reconstruction,—and consolidation of rocks, must have been vastly increased in amount, and proportioned in extent to the universal diffusion of heat; while the arrangements of organic life, which we know to be *adjusted to a certain limited range* of temperature, must have been proportionately affected. Until the mean temperature of the sea was reduced to a certain standard, the Physical conditions to which organic life is restricted on our Globe were not established; but during these periods the inorganic forces of Nature must have been especially active, and on a very great scale. Hence the vast thickness, the great degree of consolidation, the crystalline character, the almost universal extent of the primary strata; hence the rarity of organic remains, until, by the accumulation of considerable thicknesses of nonconducting earthy materials upon the bed of the Ocean, the communication of heat from the interior of the Globe was retarded, so as to be counterbalanced by that constant radiation from its surface, which is one of the conditions whereto the organization of plants and animals is adjusted.

Disturbances of the Primary Strata.

During the accumulation of the slates.

Though during the accumulation of the slates beneath the waters of the sea, considerable tranquillity and a repetition of similar circumstances prevailed, as may be inferred from the correspondence of the stratification, the rarity of conglomerates, and the general agreement of the organic remains at different points over immense surfaces, yet some remarkable exceptions occur, enough to show that the subterranean forces to which our Continents owe their present forms and elevations, were not wholly inactive. In the Cumbrian mountains, especially, we may clearly perceive the effects of some considerable local disturbance in the conglomerate rock of St. John's Vale, Barrow, and Grasmere; and the singular admixture and blending of porphyries, amygdaloids, and greenstones, with the ordinary argillaceous slates, proves evidently a great and continued developement of igneous agency *during* the deposition of the middle slate rocks of the lakes. Similar effects appear to have happened in Snowdonia, and some remarkable cases of extensive disturbance have been ascertained along the Eastward border of the Welsh slate system.

After the deposit of slates.

But immediately after the completion of the slate deposit, and before the commencement of the carboniferous system, a much more general and more violent succession of dislocations happened. At this period nearly all the primary ranges of the British Islands received their most remarkable features; and it is deserving of notice that some of the most important of the lines of elevation and depression then produced by subterranean expansion,—for instance, the Grampians, the valley of the Caledonian canal, the Lammermuir hills, and the prolongation of these ranges in Ireland, the Cumbrian, Snowdonian, and Cornish chains, and the hills of the Isle of Man,—run in the same direction from North-East to South West. This is the most striking example which the British Islands afford in favour of Elie de Beaumont's hypothesis of the accordance between the direction of the axis of a mountain group and the date of its elevation. Elie de Beaumont notices as belonging to the same period as the elevation of the Cumbrian and Cornish chains, the system of the Hundsruck in Westphalia, the country of the Eifel, and the mountains of Nassau, in all of which the principal ranges are North-East by East, and South-West by West. Other examples will hereafter be mentioned which seem irreconcilable to his views; in the mean time we may state that the contemporaneous elevation of the greywacke systems

Geology. Ch. II.

of the South of Ireland and Devonshire ranges East and West. Elie de Beaumont, indeed, distinguishes between the dates of these Eastern and Western lines of elevation, and those previously traced in a North-Eastern and South-Western direction, and refers them to a later period. The North-Eastern lines are considered to have been caused *during* the transition (slate) period, and the Eastern and Western, *immediately after* that period. This requires further examination. Professor Sedgwick attributes to the Cumbrian slates one great elevation anterior to the carboniferous system, and we may safely adopt this as a general view, though there appears good reason to doubt whether all the various Plutonic rocks mixed in so singular a manner among the conglomerate slates of Cumbria, were injected at one period.

Influence on the mean direction of strata.

In consequence of these elevations, the strata of slate thrown up towards a central ridge of Plutonic rocks exhibit amidst many irregularities prevailing dips towards the South-East and North-West, and have thus considerably influenced the mean bearing of all the subsequent deposits of British strata in which a very general tendency to the North-Eastern and South-Western direction has been for a long time observed.

Plutonic rocks are often visible along the axis of these ancient elevations. The Cumbrian chain encloses a line of nuclei of granite, syenite, and hypersthene rocks, besides various porphyries and greenstones in dykes, and overlying plateaux, of which the age is less certainly indicated. These have evidently been injected in a melted state into fissures produced during the general movement of the stony masses; but there is rarely any proof derived from veins, or from the appearances at the points of their contact with other rocks, that the central granitic masses were uplifted in a melted state. But in Cornwall, in the North of Ireland, and still more generally in Scotland, the granitic rocks were evidently in a state of fusion, since the deposit of the slates, and, accordingly, these latter rocks, and the various strata associated with them, are often penetrated by veins of granite, and materially altered at the surfaces of contact. Have the fissures occasioned by these intestine subterranean movements furnished the cavities which have since, by injection, sublimation, and segregation, been filled by various metallic and mineral substances?

Mineral veins

These *mineral veins* are, upon the whole, more numerous in the primary strata than in any of the secondary rocks; and the generally admitted fact that they are not all of the same age in the same mining country, may lead us to suppose that their production was not confined even to one great epoch in Geology, but was repeated at intervals during the whole period of the formation of the strata.

Table of the Organic Remains of the Slate System.

The mark * signifies that the species to which it is attached occurs in the carboniferous system also.

PLANTS.

Family.	Name.	Foreign Localities.
Algæ	Fucoides antiquus, Bgt.	Christiania.
	serra, Bgt.	Quebec.
	dentatus, Bgt.	Ditto.
	circinatus, Bgt.	Base of Kinnekülle, Sweden.
Equisetaceæ	Calamites radiatus, Bgt.	Bitschweiler. (Haut Rhin)
	Voltzii, Bgt.	Zundsweiher. (Baden.)
Filices	*Sphenopteris dissecta, Bgt.	Berghaupten. (Baden.)
	Cyclopteris flabellata, Bgt.	Ditto.
	*Pecopteris aspira, Bgt.	Ditto.
	*Sigillaria tessellata, Bgt.	Ditto.
	Voltzii, Bgt.	Zundsweiher.
Lycopodiaceæ	Lepidodendron. (several species.)	Berghaupten, Bitschweiler.
	*Stigmaria ficoides, Bgt.	Bitschweiler.
Class uncertain	Asterophyllites pygmæa, Bgt.	Berghaupten.
	Fossil plants generally	Near Namur.

This list, which is taken almost wholly from M. A. Brongniart's *Prodrome de l'Histoire des Végétaux Fossiles*, will be found remarkably analogous to the more extended catalogue of the plants of the carboniferous system of strata. The fourteen or more species of plants here recorded, belong to genera which occur likewise in the carboniferous strata above, and four of the species, marked by an asterisk, are found again in these rocks. Three of the four occur at Berghaupten, in coal measures which may be of the true carboniferous epoch. All the genera are, probably, extinct, though with respect to the filices this is difficult to prove, on account of the almost total want of fructification in the fossils, and their generally fragmentary state. Four species are marine, two or three probably belonged to marshes, and seven or eight or more to drier situations. The marine plants are mostly found in limestone. The number of species is too small to furnish, alone, any general inferences either as to the prevalent character of the Flora, or the climate of this period; yet taken in connection with the carboniferous system, they appear to warrant a belief that vascular cryptogamic plants were in possession of the land, that this was very limited in extent, and that the climate was hot.

Organic Remains of the Slate System.

POLYPARIA.

Family.	Name.	British Localities.	Foreign Localities.
Fibrosa	Achilleum cariosum		Groningen. (loose specimen.)

	quadrigeminum		Eifel, Bensberg.
	cæspitosum		Eifel.
	hexagonum		Ditto, Bensberg.
	helianthoides		Eifel, Lake Huron.
	Strombodes pentagonus		Drummond Island, Lake Huron.
	Astræa ananas		Gottland.
	porosa	Glouc. Heref.	Eifel, Bensberg.
	Columnaria alveolata		Seneca Sea. (New York.)
	Sarcinula punctata, Park.	Gloucestershire.	
	organum		Gottland.
	angularis, Fl.	Dudley.	
	Mastrema pentagona, Raf.		Kentucky.
	Pleurodictyum problematicum		Nassau, Hundsruck.
	Hydnophora	Shropshire.	
	*Amplexus coralloides, Sow. } Cyathoph. flexuosum? Goldf. }		Mont Chatou, near Coutances, Catskill Mountains.

In the above list the specific names are chiefly adopted from Goldfuss.

The great number and variety of the species of polyparia in strata so near in position to those which contain no traces of living Beings, is remarkable, and sets in a strong light the error of those who suppose the paucity or deficiency of organic remains in the lower strata is owing merely to their antiquity; while at the same time the almost exclusive limitation of these remains to the calcareous beds of the slate system shows that the true cause both of their rarity in the one case, and their plenty in the other, must be sought in the condition of the sea at the different periods. It is especially worthy of notice, that though nearly all the species are peculiar to the slate system, most of the genera are repeated in the carboniferous limestone above, and several exist in the present sea, as madrepora, astræa, cellepora, retepora, gorgonia.—Types of all the most remarkable living tribes of polyparia are preserved in these ancient repositories; the lamelliferæ bear the same large proportion to the other corals as now obtains in hot seas, and it is evident that the general arrangements of Nature with respect to the life of marine animals were of the same kind as at present.

With respect to the Geographical distribution of the species our Catalogues and our Collections appear to present a remarkable contrast; for while the former seem to show that a very few species only have been recognised at more than one locality, the general impression derived from a view of the latter is exactly the reverse. The systematist is perhaps too easily led to multiply distinctions without necessity, while the eye of the ordinary observer is more easily imposed on by the analogy of kindred forms. At all events, it is certain that the zoophites of this limestone are eminently characteristic of it, and some of the genera may almost be taken to represent it: such are favosites, catenipora, amplexus; and yet these all occur (less abundantly) in the carboniferous limestone.

Organic Remains of the Slate System.

RADIARIA.

Family.	Name.	Rock.	British Localities.	Foreign Localities.
Crinoidea	Pentremites florealis, G.	Calcareous		Mississippi.
	Caryocrinus			North America.
	Eugeniacrinus mespiliformis, G.	Ditto		Eifel.
	Pentacrinus priscus, G.	Ditto		Ditto.
	Platycrinus ventricosus, G.	Ditto		Ditto.
	*pentangularis	Ditto	Dudley, Din vawr.	
	Cyathocrinus tuberculatus	Ditto	Dudley.	
	*rugosus	Ditto	Shropshire	Oeland, Dalecarlia, Eifel.
	geometricus, G.	Ditto		Eifel.
	pinnatus, G.			Ditto.
	pentagonus, G.			Groningen.
	Actinocrinus moniliformis	Ditto	Dudley.	
	*30-dactylus			Eifel.
	lævis			Ditto.
	cingulatus, G			Ditto.
	muricatus, G.			Ditto.
	nodulosus, G			Ditto.
	moniliferus, G			Ditto.
	Melocrinus hieroglyphicus, G.			Ditto
	gibbosus, G.			Ditto.
	*Rhodocrinus verus		Dudley	Ditto.
	gyratus, G.			Ditto.
	5-partitus, G.			Ditto.
	canaliculatus, G			Ditto.
	crenatus, G.			Ditto.
	Cupressocrinus crassus, G.			Ditto.
	gracilis, G.			Ditto.
	tesseratus, G.			Ditto.
	Eucalyptocrinus rosaceus, G.			Ditto.
	Echinosphærites pomum, W.			Oeland, Kinnekülle, near St. Petersburgh.
	aurantium, W.			Mösseburg, Westrogothia.
	granatum, W			Oeland, Dalecarlia.
	Wahlenbergii, E.			Gulf of Christiania.
	Encrinites Gothlandicus, W.			Gottland.

In the preceding list of radiaria, all the species named by other authors than Miller, have the initials of those authors, as Goldfuss, Wahlenberg, Esmark. The thirty-four species here collected have all vanished from the present ranks of Creation, but we find at least four repeated in the carboniferous limestone. Six of the thirteen genera are also continued into that limestone, and two, (eugeniacrinites and pentacrinites,) the latter of which is unknown in carboniferous limestone, are rather plentiful in the oolitic rocks. The crinoidea of the slate system are almost exclusively found in limestone, and only locally distributed in that rock. No true echinida or stellerida have yet been described from these ancient rocks.

All the leading divisions of living conchifera are recognised in the shells of the slate system, but there is a singular contrast between the present and the ancient systems, as to the relative proportions of these divisions. A short tabular comparison will render this very evident.

Of 100 conchifera now living 80 are plagymyonous; 18 mesomyonous; 2 brachiopodous: belonging to the slate system, 27 are plagymyonous; 11 mesomyonous; 62 brachiopodous. Of 78 species belonging to plagymyona and mesomyona, 3 are repeated in carboniferous limestone, and 10 of the 11 genera which include them are continued through a long range of secondary rocks.

Nearly all the genera (as yet imperfectly understood) of the brachiopodous bivalves are also found abundantly in carboniferous limestone. Of all these, terebratula is the only one now living, and it is very correct to say that the forms of these "primary" species recede much more from the living terebratulæ than do those of the less ancient secondary strata. The muscular and ligamental structure of these animals, could it be well made out, would surely afford very curious results. The shells are most frequent in the limestones, but not by any means confined to them. Of 129 species included in the preceding lists, 17 occur also in the carboniferous limestone, and for the most part abundantly. The localities in which these shells are stated to occur in transition limestone are, Plymouth, Newton Bushel, and Torquay in Devonshire, 10 species; Isle of Man, 2 species; Herborn, Blankenheim, and the Catskill Mountains. We must leave it to future observers to say, whether any other such coincidences occur at these and other places, and whether it is quite certain that the limestones of Devonshire really belong to the transition series, a point on which we cannot avoid feeling some doubt.

The following conchifera, chiefly collected by Mr. Weaver from limestone in the South of Ireland, are referred by M. De la Beche to the transition limestone. We have found in comparing this list with that of fossils indubitably belonging to the carboniferous epoch, so extraordinary an identity, and on the other hand, when compared to characteristic fossils of transition limestone obtained from Countries in which its Geological relations are certain, so marked a discordance, that we must for the present keep the fossils from the South of Ireland separate.

The mollusca of the slate system range themselves under 16 gasteropodous and 8 cephalopodous genera. There are stated to be 64 species of the former and 79 of the latter. The gasteropodous genera are mostly thought to be identical with those now in existence; excepting nautilus, all the cephalopoda are extinct generically. All the species are extinct, though N. caurena, Lam., is (we suppose by mistake) quoted as found in America.

The ammonites of this system are of the same generic types as those in the carboniferous limestone, with waved or angulated, but not foliaceous sutures.

From the South of Ireland we have,

Melania constricta.*
Pileopsis vetusta.*
Nerita.
Cirrus acutus.*
Euomphalus catillus.*
Pleuromaria cirriformis.
Bellerophon tenuifascia.*
ovatus.
Orthoceras striatum.
paradoxicum.
Nautilus globatus.*
Nautilus multicarinatus.*
cariniferus.*
(Ellipsolithes) funatus.
compressus.
ovatus.
Ammonites.

In which list the asterisks show analogy to the carboniferous limestone, while perhaps not a single fossil is characteristic of the transition series.

Out of 143 species of mollusca in this list, 16 are marked as also occurring (for the most part plentifully) in the carboniferous system. The localities which produce these shells are the Devonshire limestones before mentioned, Blankenheim, Lake Erie, Shropshire, and the country about New York. We recommend the further consideration of this subject to the special attention of Geologists, in connection with Mr. Murchison's recent discoveries in the upper slate system of Wales, in which all his researches appear to show a constant and complete difference between the fossils of the transition series and those of the carboniferous limestone, separated from it by four thousand feet of old red sandstone.

The greater part of these crustacea are peculiar to the slate system, and are distributed extensively along its range, generally in the upper slates and calcareous beds. No trilobite has yet been found in these strata in Scotland, Cumbria, Cornwall, or Ireland, but many species occur at Dudley, in Shropshire, Herefordshire, and South Wales, as well as in Sweden, Norway, about St. Petersburg, the Harz, the Eifel, at Angers, and in North America. Several species yet undescribed belong to the carboniferous limestones of England, which appear different from those of the transition limestone.

Fishes.

Traces of fishes have been found at Dudley, Tortworth, and in the Eifel.

General Summary.

There are 553 species of organic remains, of which 49 are also found in the carboniferous limestone *more abundantly*. The principal localities for these species in the slate system are Devonshire and the banks of the Rhine. If we include the shells of the South of Ireland, the repetitions of species amount to 62.

Plants	14	species, of which 4 are marine, 10 terrestrial.
Polyparia	87	fibrosa 7, corticifera 2, cellulifera 44, lamellifera 34.
Radiaria	31	
Conchifera	206	plagymyona 55, mesomyona 23, brachiopoda 128.
Mollusca	143	gasteropoda 64, cephalopoda 79, of which 11 are monothalamia.
Annulosa	4	
Crustacea	65	
	553	species, all marine, except a few plants.
Fishes		

Secondary Strata.

Carboniferous System.

Physical geography of the period.

At the commencement of the second great period in the deposition of the stratified crust of the Earth, that during which the secondary strata were deposited, the surface of the Globe, as far as this can be known from observations so long posterior, was in a very different state from that which has been inferred to have been its condition before the deposit of the primary strata. *Then* it is probable that little dry land existed, and perhaps most of the mechanical aggregates of the primary series were produced by agitations of the comparatively shallow waters of the Ocean; but *now* many mountain ranges and groups may be traced dividing the Ocean into seas and gulfs of various depths and unequal area, within which materials swept forcibly by inundations from the land were mingled with chemical precipitations from the water. Thus the primary ranges of Scotland, England, Wales, and Ireland, the South of France, and the North of Germany, are in many parts enveloped in thick strata of conglomerate sandstones, shales, coal, and limestone; and these deposits begin to assume more local characters, dependent on the varying Physical conditions of the particular case.

The shales and sandstones, which are evidently the result of the mechanical action of water, contain the reliquiæ of plants in great abundance, and the coal seams are wholly formed from the matter of terrestrial vegetables; but the limestones are full of marine shells, corals, and radiated animals. From the former we learn the condition of the land, from the latter that of the sea. The high temperature during the deposition of the primary strata, indicated by the remarkable consolidation of the rocks before the carboniferous era, may likewise be inferred from the tropical character of the plants associated with the coal seams, and the coralline and other zoophytic animals embedded in the limestones of the carboniferous epoch. To this period likewise belong many mineral veins, many eruptions of basaltic rocks, and other effects of internal heat.

The carboniferous deposits are generally very distinguishable from those of the primary group; most remarkably so, where, as is generally the case, their accumulation was preceded by a great elevation of the slate mountains: but in several instances the change from the older slates to the shales and sandstones of the superior group is very gradual, (*Herefordshire*,) and unaccompanied by violence, and the organic remains are mostly congenerous. It is not then a new Creation, nor even a new System of Nature, that we are called upon to examine, but another step in the scale of periodical operations, whereby the vacant Planet was replenished with life, and fitted for the residence of Man.

Divisions of the system.

In England the carboniferous system, when fully expanded, admits of division into three series:

The old red sandstone,
The carboniferous limestone,
The coal formation;

and in many parts, (Somersetshire, Monmouthshire, Derbyshire, &c.) these are not only distinguishable but even strongly contrasted; the first by its red sandstones, and conglomerates derived from the neighbouring primary mountains; the second by its almost undivided mass of limestone full of marine exuviæ; the last by its shales and argillaceous sandstones, bands of ironstone, and beds of coal. But, in Yorkshire, the limestone series begins to be intermingled with coal, sandstones, and shales; in the Northern parts of Northumberland these two series are intimately blended; and in the Island of Arran the diminished deposits of coal and mountain limestone are included, and almost lost in one vast mass of red sandstone, with no clays and conglomerates.

There is nothing peculiar in this: we shall find exactly similar phenomena among the superior formations. In fact, it is certain that among all the formations posterior to the slates, the distinctions of strata are mostly local, and even the formations themselves, however extensive, are limited within the circuit of the anciently elevated primary mountains. Nevertheless, the red conglomerates when present usually appear at the base of the carboniferous system, and the coal deposits are most plentiful at the top. This appears a natural consequence of the state of the Earth's surface when the formation began. The conglomerates should be most abundant in the oldest deposits, because they are evidently the result of the transient violence attending the elevation of the primary strata which they surround; then, in the sea, the period of succeeding tranquillity is marked by the most decided accumulation of marine spoils; and these, according as they took place in deep water or near the shore, retain a pure oceanic character, or are mingled with the spoils of the land, which, increasing in quantity, finally buried them under the vast mass of coal measures.

In describing this series we shall confine ourselves principally to the British Isles.

Old Red Sandstone Formation.

Origin of this formation.

In most cases the production of this rock is evidently the effect of general convulsive movements. The slate rocks of Cumbria, exposed upon their recent elevation to enormous waste and degradation, were rolled to pebbles, which were collected into hollows or rude valleys, and reunited by a basis of red sandstone or red marl into vast irregular beds of coarse conglomerate.

The mountains of Scotland are in the same way bordered by enormous accumulations of the same character; and those of North and South Wales are flanked by extensive deposits of pebbly red sandstone.

This lowest member of the carboniferous system, though varying in character in every different cliff and district, and irregularly distributed, is an extensive and important mass of strata.

In the Cumbrian district.

The limited tract of old red sandstone adjoining to the slate district of Cumberland and Westmoreland, lies principally on the Eastern side, where it appears in patches, in Mell-fell, at Dacre Castle, Sedbergh, and Kirby Lonsdale, and near Kendal. In all these situations it is a very coarse conglomerate, with a basis of red sandstone or red marl, filled with fragmented masses, almost entirely derived from the neighbouring slate hills. Some of these fragments are quartz veinstone with micaceous iron ore. Each little patch of conglomerate is nearly confined to a particular valley, and seems, in fact, to have been accumulated by currents which in the ancient times of disturbance passed down that hollow. No organic remains have ever been found in this rock around the district of the Lakes. In some places the quantity of pebbles is diminished, and the red sandstone forms separate beds; (Shapwells;) in other places the red clay, alternating with blue and white layers, (as at Kirby Lonsdale,) so closely resembles the new red marl, that nothing but the Geological relations could determine the difference of the deposits. As might be expected in such a heterogeneous mixture, the beds and joints of the conglomerate beds are irregular, and it deserves attention that hitherto no mineral veins have been found to traverse it. Veins of calcareous spar occasionally divide it, and, what is remarkable, the pebbles are often split by these veins, as they are in the contemporaneous conglomerate of Oban in Argyleshire, and the more recent Nagelflue of Swisserland.

It appears from these circumstances, that during the period of turbulence which succeeded the deposit of the slates in Cumberland, the waters of the sea had a particular tendency to deposit, near the shores, materials charged with red oxide of iron, and that the comparatively quiet process by which sandstones and clays were thus produced was liable to violent interruptions, and the products in consequence mixed with a vast quantity of fragments of the preconsolidated rocks, probably urged downwards to the sea along the lines of dislocated strata which had already begun to be excavated into valleys.

In Wales.

Along the South-Eastern and Southern border of the slate district of Wales, through Herefordshire, Monmouthshire, Glamorganshire, and Pembrokeshire, the old red sandstone formation is much more fully developed than in the lake district of the North. It is vastly thicker, more extensively spread out, composed of various definite parts, and consequently more regularly traceable through the country. Its boundary on the West is by Caermarthen, Brecon, and Leominster. On the East it runs from near Cardiff, by the high district of Wentwood, Trelech, and Craig y Dorth, and by the Forest of Dean, which it encircles with a high boundary edge to near Leominster, where it seems to end abruptly. Its thickness in Monmouthshire and Breconshire can hardly be estimated at less than 2000 feet; but its lower edge is not always clearly distinguishable from the greywacke slates beneath.

Monmouthshire, &c.

One of the best sections of the old red sandstone is afforded in the neighbourhood of Monmouth, beginning with the Kymin Hill, which is part of the lofty boundary of Dean Forest.

Here we perceive that the thick conglomerate rocks, full of quartz pebbles, remarkably analogous to some varieties of millstone grit, form the very cap of the whole system, and crown the hills with magnificent precipices and solitary crags. Below is a series of red sandstone rocks, productive of excellent flagstone, with one, or perhaps two, beds of a singular limestone, mottled with red, blue, green, and yellow, sometimes much mixed with clays, and always irregular. Though of argillaceous aspect, it is so nearly pure as to be burned to lime; and though apparently fragmentary, is really a very hard stone, fit for the roads. It contains no organic

remains. The lowest part of the section exhibits an extreme abundance of red marls with white and green bands, undistinguishable from those of the new red marl.

These characters accompany the range of the old red sandstone through the lower parts of Monmouthshire, and through Herefordshire, and part of Worcestershire, where the upper conglomerates are used as cyder mill-stones, and the limestone (called cornstone) is often employed on the roads.

This limestone, indeed, notwithstanding its apparently irregular and fragmentary character, is one of the most persistent layers that we are acquainted with, for it accompanies and characterises the old red sandstone along nearly its whole course. In Caermarthenshire it is particularly remarkable in the cliffs near Laugharne, from which specimens may be obtained not distinguishable from the "gooseberry" stone of Monmouth.

Scotland. The old red sandstone is largely developed in Scotland, especially along the South-Eastern edge of the Grampian mountains, and on the North-Western side of the slate ranges of Lammermuir, as fully described by M. Boué. As before observed, it forms in Arran the lower portion of one vast red sandstone series, the upper portion of which, not very different in any of its characters, is taken by Murchison and Sedgwick for the representative of the new red sandstone of England.

On the Western side of Scotland the old red sandstone is found at many scattered points in bays and hollows of the mountains, and has received very good illustration from Macculloch and the Geologists above named. Along the Caledonian Canal and in Caithness, strata of this age abound, and the Orkneys appear to consist chiefly of the same group of rocks.

Almost universally this red sandstone system, how various soever in thickness and in quality of composition, consists in all the lower portion, which rests upon the slate system, of a coarse conglomerate sandstone, generally tinged red, full of fragments large and small, and rounded by attrition in water. This rock does not, like that of Cumberland, to which it is strongly analogous in composition, lie entirely in local hollows, but forms a continuous belt round nearly the whole primary district, where the border of this is distinctly seen, and rises into hills of considerable altitude, which are in this manner wholly composed of the ruins of the interior and still higher primary mountains. The contemplation of this remarkable rock in the vicinity of the beautiful Lakes in the South-West part of the Grampians, can hardly fail to impress upon the attentive observer two propositions of the highest importance in Geology. 1st. That the accumulation of these mountainous ruins of earlier rocks was caused by the violence of water, put into activity by the elevation of the primary rocks, and favoured in operation by the fractures which this operation produced in them. 2d. That, since all these effects, the whole region of primary and derivative rocks has been again elevated, perhaps by a more insensible process, so as to raise the conglomerates to the height of 1000 feet or more above the level of that sea in which they were formed.

According to the nature of the primary rocks in its vicinity, as remarked by M. Boué, the red sandstone conglomerate varies in composition. The degree of attrition to which the fragmentary masses which it includes have been exposed, is here different in different places; without doubt according to the degree and continuity of the aqueous action accompanying the disruption of the primary strata. Thus on the banks of Lochness, at the Fall of Foyers, we find it a sort of granitoid breccia, with fragments slightly rolled of quartz, mica slate, red granites, primary limestones, &c. We might easily admit that this granitoid breccia is in some degree *metamorphic*, like certain breccias of Plutonic aspect in the slate district of Cumberland. The brecciated character, so remarkable at the Fall of Foyers, is speedily changed at a small distance into the usual aspect of a decided conglomerate.

Along the South-Eastern edge of the Grampians, the composition of the conglomerate appears dependent in a high degree on the nature of the primary series on which it reposes. Near the granitic and porphyritic region of Aberdeenshire, quartz, felspar, porphyry, granite, with garnets, sienite, hornblende, compact felspar, are mentioned by Boué, with gneiss, mica slate, and clay slate. But in the district of Loch Katrine, where Plutonic rocks are less abundant in the slate system, the fragments consist almost wholly of mica and chlorite slate. In Oban we have observed that the rock contains not only masses of trap rocks, but that its base is in places almost wholly composed of the substance of those rocks, reduced to sand. Along the Lammermuir ranges, which are composed of clay slate and trap rocks, the conglomerates contain almost wholly slate fragments and boulders, and lie in hollows of the chain, very much as the contemporaneous deposits border the similar slates of Cumbria.

The inclination of the conglomerate strata is dependent on the configuration of the primary mountains, and there is no doubt that the stratification is for great lengths of country in irregular accordance with that of the older rocks; yet this dependence is chiefly observed along the lines parallel to the axis of elevation of the Grampians, and is even there liable to great exceptions. In the vicinity of Loch Lomond it succeeds clay slate; generally along the Grampians it rests on mica slate or chlorite slate; but along the Lammermuir hills on greywacke slate.

Receding from the border of the mountains, the upper strata of red sandstone are found nearly free from pebbles, composed of laminæ of various quality, sandy or argillaceous; and sometimes, as in Perthshire, variously coloured. The greater part of the sandstones of Caithness, which are usually ascribed to this era, are dark, carbonaceous, flagstone rocks, in a few places containing between their layers very interesting specimens of fishes, which have been conjectured to belong to fresh-water tribes. Laminated sandstones abound in the Orkneys. Red sandstones accompany the coal of Dumfriesshire, and in this part of Scotland we believe that the red sandstone series is, like that of Arran, a great continuous deposit, in which the carboniferous limestone and coal seams form merely the parting, not always traceable, between the old red and the new red sandstone systems. A natural classification, in all the Southern parts of Scotland, made without reference to other parts of the Island, would, we think, include the carboniferous and saliferous systems in one general term, the *red sandstone system* having, as subordinate groups, *the mountain limestone and coal strata.*

This should diminish the anxiety sometimes felt about *universal agreement in classification*, and encourage topographical Geologists to employ for the country they describe the arrangement of strata most suitable to develope the true local relations of the rocks.

Metallic veins are rare in the old red sandstone rocks,

but veins of crystallized earthy substances occur frequently. Carbonate of lime traverses it at Kirby Lonsdale; sulphate of barytes near Monmouth and South Saunox in Arran; sulphate of strontian occurs in it near Inverness; and asbestus in Kincardineshire. (Boué.) The joints in it are very irregular.

In Ireland. The mountain limestone, which underlays all the coal fields of Ireland, generally rests on old red sandstone, which is unconformable to the subjacent slates.

Mountain or Carboniferous Limestone Formation.

The carboniferous limestone is a rock of which the history must principally be studied within the limits of the British Islands, for it is no where else so much or so variously developed. Its romantic rocks border many of the most beautiful valleys of the South-West of Scotland, Northern and Central England, and encircle the wide primary regions of Wales. In Ireland, as Mr. Weaver observes, this limestone is the prevalent and characteristic rock in most of the Counties, except Derry, Antrim, and Wicklow.

The romantic channel of the Meuse runs for a considerable distance about Namur and Liege in a very remarkable range of carboniferous limestone, along the Northern side of the primary slates of the Ardennes, and is prolonged Eastward to the German side of the Rhine, near Dusseldorf, and continued Westward (beneath a wide deposit of chalk) to the neighbourhood of Boulogne. The coal deposits of Poland are based upon dark limestones of the same age as the carboniferous limestone of England, but in general the coal fields of the centre and South of France, of Saarbruck, of Saxony, Silesia, &c. appear to be devoid of this rock; but Mr. Murchison mentions its occurrence in the North-East of Bavaria and in Bohemia. It abounds in North America, accompanying coal and anthracite.

It has been before remarked, that the carboniferous limestone presents itself with a very different aspect in the Northern and Southern Counties of England. In Somersetshire, Gloucestershire, Shropshire, South Wales, North Wales, Derbyshire, and Leicestershire, this rock appears an immense, nearly undivided, calcareous mass, perfectly defined below by a hard contrast with the old red sandstone or greywacke slate which supports it, and as distinct above by the abrupt covering of sandstones and shales which accompany the coal.

Very rarely indeed in the Southern Counties, as in the rocky valley of the Avon at Clifton near Bristol, are any beds of red sandstone interpolated among the lowest strata of limestone; and it is only by a few unimportant partings of shale that the upper portion is at all assimilated to the incumbent series. The toadstones which irregularly interlaminate the thick limestones of Derbyshire are of igneous origin, and it is not, in proceeding Northward, till we arrive in the valley of the Ribble, that any decided alternation of mechanical deposits breaks into distinct groups the strata of carboniferous limestone. From this point Northward, almost in the ratio of distance, to the banks of the Tweed, the limestone becomes more and more divided by beds of sandstone and shale, accompanied by ironstone, fossil plants, and coal; and thus, under Ingleborough we have a nearly undivided calcareous mass 400 or 500 feet thick; but at Aldstone Moor no less than twenty different limestones, amounting altogether to 470 feet, obscured by the interposition of no less than 1686 feet of sedimentary strata.

Further North these mechanical admixtures increase in amount, while the calcareous strata diminish, and at length, in the Northern parts of Northumberland, the limestone district has become a valuable coal field.

To embrace the subject in its most interesting point of view, we shall commence our account of the carboniferous limestone with a description of its characters in the "Pennine Alps," which border the Western parts of Yorkshire and Durham, and the Eastern parts of Cumberland and Westmoreland, and we shall connect therewith the analogous arches of limestone, which begird the primary district of the Cumbrian lakes. Taking this as a type of the formation, we shall be able to compare with it the other localities in the British Isles and on the Continent of Europe.

This tract of country has been, for different objects, partially described by Professor Sedgwick and other Geologists, and their views, whether published or not, will be recognised in the following summary. The Cumbrian slates are surrounded for three-quarters of a circle, from Egremont to Ulverston, by a belt of limestone, which reposes indiscriminately upon the lower slate near Loweswater, the middle slates near Ulswater, the upper slates from Shap to Ulverston, and the old red conglomerate at the several points of Dacre, Sedburgh, Barbon, Kirby Lonsdale, and Ulverston.

The South-Eastern part of this circular belt forms part of a long range of limestone cliffs facing the West from Ingleborough to Tindal Fell, defined by one continuous line of elevation nearly 1000 yards in height. Prodigious transverse dislocations occur at these points, that at the Northern end ranges East and West, and causes an immense depression to the North, after which the limestones range North-East through Northumberland; that at the Southern end ranges West South-West and East South-East, and causes an equally striking depression to the South, after which the limestones show themselves locally, and in much disturbance, as far South as Clithero.

From the high Western escarpment before mentioned, the strata sink with a very regular inclination Eastward or South-Eastward, and are exposed in the valleys of the South Tyne, Derwent, Wear, Tees, Greta, Swale, Yore, Ribble, Wharfe, Nid, and Aire, bordering those streams with some of the boldest and most picturesque rock scenery in England.

The grand natural section of Ingleborough and Penygant presents us with the following series of rocks belonging to the carboniferous limestone.

		Feet.
1. Group above the limestone, commonly called millstone grit series	Alternations of sandstone and shale with bad coal on Penygant	100
	Millstone grit of Ingleborough	60
	Alternations of sandstone and shale	100
2. Upper belt of limestone	Thin limestone 8 feet; Shale 10; Main Great limestone 60	78
3. Alternations principally of shales and sandstones, some of them flagstones, with thin limestones		300
4. Great scar limestones with calcareous conglomerate beds at bottom		400

This series rests on slate rocks.

Proceeding Northward from Ingleborough we arrive in Wensleydale or Yoredale, and find the section modified as under:

		Feet.
Millstone grit series. 1. Above the limestone.	Coarse and fine sandstones, shales, and COAL. Coarse, fine, and slaty sandstones, shales, cherty beds, and COAL. Millstone grit of Ingleborough, shales, cherts, and COAL.	700
2. Upper limestone belt.	Thin limestone, sandstone, shale. Main or twelve fathom limestone. Shales sandstones and COAL, underset limestone.	200
3. Flagstone system.	Alternations of flagstones of various quality, in great abundance, with shales, COAL, hard gritstones, and three or four strata of limestone, from 6 to 30 feet thick. The black marble of Dent is nearly at the base of this group.	500
4. Scar limestones.	Limestones of great thickness, with partings principally of shale.	500

The series is incomplete, other limestones existing below.

Here it will be perceived the group No. 4. has become divided into distinct parts; and the calcareous portions of No. 3. are also more defined and more important. No. 2. has assumed that character of a decidedly double belt, which henceforward distinguishes it for a great distance to the Northward.

Our next station will be taken in Swaledale.

			Feet.
1. Millstone grit series.	Coarse gritstones, shales, finer sandstones, shales, and COAL.	600	800
	Variable series of thick shales, with sandstones and COAL, and local interpolations of limestone and chert.	200	
2. Upper limestone belt.	Limestone	3	252
	Shale, &c	63	
	Main or twelve fathom lime	72	
	Grit, chert, shale, and COAL	96	
	Underset lime	18	
3. Flagstone system.	Variable alternations of gritstone, flagstone, and plate, with three or four limestones from 6 to 30 feet thick.		340
4. Scar limestones	Of great thickness, but only partially exposed in the bottom of Swaledale		

The groups 1 and 3 have now become more complicated, and require further division as compared with the Ingleborough section, and thus we are gradually conducted to the still more developed series of Aldstone Moor, as described by Forster.

Group			Calcareous beds. yds. ft. in.	Other deposits. yds. ft. in.
1. Millstone grit series.		Alternations of sandstone, (coarse and fine) and shale		25 1 0
	1.	Felltop lime	1 1 6	
		Alternations of laminated and other sandstones, shales, ironstone, and COAL		109 2 8
2. Upper limestone belt.	2.	Limestone	3 0 0	
		Alternations, plate, &c. with COAL		16 2 0
		Limestone	21 0 0	
	3.	Parting		10 0 0
	4.	Limestone	0 1 6	
		Sandstone and shale and COAL		23 1 0
	5.	Underset limestone	8 0 0	
3. Flagstone system.		Sandstone and shale (Nattriss Gill Hazle)		17 0 0
	6.	Limestone	3 0 0	
		Sandstone and shale		15 1 6
	7.	Limestone (5 yards)	2 1 6	
		Sandstone and shale		10 0 0
	8.	Scar limestone	10 0 0	
		Thin alternations		15 0 0
	9.	Cockle-shell limestone	0 2 0	
		Alternations		5 2 6
	10.	Limestone (single post)	2 0 0	
		Alternations		20 0 0
4. Horn limestone.	11.	Tyne bottom limestone	8 0 0	
		Alternations in the upper part of which the "Whin sill" (igneous) occurs, (20 to 40 yards thick)		24 2 6
	12.	Jew lime	8 0 0	
		Alternations		8 2 6
	13.	Little lime	6 0 0	
		Alternations		30 0 0
	14.	Smiddy lime	10 1 6	
		Sandstone		4 0 0
	15.	Limestone	8 1 6	
		Alternations		7 0 6
	16.	Robinson's lime	7 0 0	
		Alternations		4 0 0
	17.	Great limestone, Melmerby scar	44 0 0	
		Alternations and COAL		8 0 0
	18.	Limestone	4 0 0	
		Alternations		55 0 0
	19.	Limestone	2 1 6	
		Alternations and COAL		73 2 0
	20.	Limestone	6 0 0	
		Alternations		78 0 0
			156 2 0	562 0 2

It is probable that even this section does not show us the full depth of the series.

We have for some time been occupied in endeavours to ascertain *exactly* the line which in the Aldstone section separates the groups 3 and 4 of Yorkshire, and the above result is very near the truth.

Combining together the preceding statements, we have the following results in total thickness:

Group.	Penygant.	Wensley-dale.	Swaledale.	Aldstone Moor.
1. Millstone grit series (incomplete series)	260+	700	800	409
2. Upper limestone belt.	80	200	250	247
3. Alternations, or flagstone system	300	400	250	304
4. Scar limestones	400	250+	120+	1196

In the following table the relative proportions of the calcareous and the other deposits are estimated:

Group.	Penygant. Limestones.	Penygant. Other deposits.	Wensleydale. Limestones.	Wensleydale. Other deposits.	Swaledale. Limestones.	Swaledale. Other deposits.	Aldstone Moor. Limestones.	Aldstone Moor. Other deposits.
1.	?	260	?	700	10	790	4	403
2.	70	10	100	100	93	157	97	150
3.	30	270	50	350	40	210	54	250
4.	400		150+	–100	80+	– 40	313	883
	500	540	300+	1250+	223+	1197+	468	1688

We must remark that this comparison is imperfect, because the sections are not in each case defined above or below by the same beds: in order to obtain a fairer numerical comparison, we may omit altogether the beds above the upper limestone belt, and, on account of its incompleteness, the fourth group in Wensley Dale and Swaledale.

We shall then have the following corrected scale:

	Penygant.		Wensley-dale.		Swaledale.		Aldstone Moor.	
Upper limestone belt	70	10	100	100	93	157	97	150
Flagstone system	30	270	50	350	40	210	54	250
Scar limestones	400	—	—	—	—	—	313	883
	500	280					464	1283

Had we, instead of Penygant, chosen Great Whernside for our section, we should have had the limestone of these groups about 100 feet, and the other deposits less than 200 feet; and if we had taken a section in Northumberland, instead of Aldstone Moor, the limestones would have been less than 200 feet, and the other deposits probably nearer 1000 feet. The principal changes, as we proceed Northward, appear to happen in the

Geology. Ch. II.

ower part of the limestone group, which loses its individuality by admitting between its beds a constantly increasing quantity of mechanical admixtures, and at length becomes a subordinate feature in a country which has the characters of a coal field. We shall now trace the course of the carboniferous limestone round the Cumbrian mountains, and through other parts of England.

Range of the mountain limestone.

The lower, or as we shall name it "scar limestone" group, passes Westward from Ingleborough by Kirby Lonsdale, Burton, and Cartmell to Ulverstone and Dalton; extending Northward to Kendal. (See Smith, *Geological County Maps.*) This group every where possesses the almost wholly calcareous character which it bears in Ingleborough. On the South of Ulverstone, it is covered by the intermediate grit and plate series with traces of coal, and a more extensive deposit of this kind South of Kirby Lonsdale, yielding useful coal and flagstone, is again overlaid by the upper belt of limestone and afterwards by the millstone grit series towards Lancaster.

Under Wild Boar Fell, on the borders of Yorkshire and Westmoreland, the scar limestones begin to exhibit, in consequence of dislocations, a double escarpment, the Western branch passes off by Ashfell, Orton, Shap, and Lowther, to the Eamont, and continues by Greystoke Park, Hesket, Ireby, and Cockermouth to Egremont. These limestones alternate in their lower parts with red sandstone, by some Geologists referred to the old red, and diminish in thickness Westward. They are overlaid by deposits of the grit and shale series near Shap, Hesket, Newmarket, and Bolton, but from Workington to Whitehaven the thick and abundant coal seams probably belong to the ordinary coal series above the millstone grit. There is, perhaps, unconformity here between the coal measures and the limestone, a case very rarely observed in England.

Agreeably to what has been said before the scar limestones, in passing through Northumberland, become continually more and more subdivided by interpolations of sandstone, shale, and coal, till on the sea-coast North of Belford, a part of this series contains no less than thirteen bands of limestone, (121 feet in total thickness,) separated by many times their thickness of sandstone and shale, and under the whole lie workable seams of coal. The character of the surface of all the Western and North-Western part of Northumberland corresponds to this change of the component strata. Instead of the beautiful green pastures which delight our eyes amidst the calcareous dales of Derbyshire and Yorkshire, wide, heathy, and boggy moorlands overspread the surface of sandstones and shales, and we seem to wander in a region of barren coal measures rather than on the range of the thickest carboniferous limestones. This may serve to explain the seeming anomaly in Mr. Greenough's Map, where this unquestionably carboniferous tract is represented as distinct from any of the strata in the British section. Mr. Smith colours the whole space as a coal tract.

On the contrary, in proceeding Southward along the [chain]ble, we find the lower scar limestones in great force about Clithero, surmounted by a considerable mass of shales with sandstones, corresponding to the shale and grit series of Ingleborough; above these, in Pendle Hill, appears the diminished upper belt of limestone, and, over all, the millstone grit series, here also occasionally yielding coal. Hence to Derbyshire, the scar limestones lie too deep to be seen, and the upper belt of limestone appears to be extinguished; so that this part of the Western boundary of Yorkshire is occupied by a vast thickness of the millstone grit series and the flagstone series, without any disclosure of the subjacent limestones, even in the deeply excavated valley of Todmorden.

In Derbyshire, putting out of the question the irregular interpolations of igneous rocks, called toadstone, we have the scar limestones more than 750 feet thick, surmounted by shale with their alternations of sandstone, *limestone*, ironstone, &c. 500 feet, and the hills are crowned by bold ranges of millstone grit, and its accompanying sandstones, 360 feet in thickness.

See pl. i. fig. 15. which expresses in general terms the *method of variation* of the carboniferous limestone and millstone grit series of the grand Penine chain.

South of Derbyshire we have no longer the same remarkable mass of strata interposed between the scar limestones and the proper carboniferous sandstones and shales. The limestone, wherever it occurs in North Wales, Shropshire, the Forest of Dean, Mendip, and round the coal field of South Wales, refers itself to the type of the scar limestones of Derbyshire, and it is only by a very imperfect representative in Shropshire and the Forest of Dean, and on the Northern border of the coal field of South Wales, that the millstone grit series can be recognised.

The limestone tract along the Meuse is evidently of the same era as the limestone of Derbyshire and Monmouthshire, and continually recalls to the delighted voyager the beauties of the Derwent and the Wye, but the strata above it are with difficulty compared with those of any part of the English basins.

Having thus compared in the most general point of view the component groups of the carboniferous limestone and millstone grit series in different localities, and ascertained the method of variation which it observes, we shall endeavour to describe some of the principal characters of these several groups.

Scar Limestones.

General characters of the rock

The carboniferous limestone, though by no means of one uniform aspect or chemical composition, possesses, nevertheless, a certain range of mineralogical characters which are scarcely to be recognised in any of the other secondary calcareous deposits. It is usually a nearly pure carbonate of lime, of a greyish or even very blue tint, of considerable hardness, and imperfect conchoidal fracture. Some of the varieties are very dark coloured, and even quite black, (Swansea, Abergavenny, Kilkenny, Derbyshire, Yorkshire,) but the latter commonly contain a minute admixture of argillaceous and bituminous matter. Many varieties exhale a fetid odour on being rubbed or bruised. In Derbyshire, and generally along the Yorkshire and Westmoreland ranges, the scar limestones contain considerable beds of a granular and even brecciated limestone capable of being employed as good freestone, and some layers in Derbyshire and Westmoreland appear almost wholly composed of crystalline grains, and contain magnesia. A crystalline variety in Derbyshire is mixed with red oxide of iron. In the country about Burton in Kendal, and Clifton, near Bristol, the stone is often decidedly oolitic, and even exhibits considerable variety in this respect. The lower layers which rest upon the slate on the Craven mountains, at Kendal, and near Penrith, are filled with large and small boulders of the slate, so as to become a real conglomerate.

But the most decided characters of these rocks are the organic remains, all of which are different from those of the strata above. The prodigious abundance of productæ, spiriferæ, terebratulæ, and other shells, of lamellated corals, and above all, of crinoidal remains, will almost always enable even the tyro to pronounce on the identity of the mountain limestone. Crinoidal remains, in particular, are so excessively abundant in certain parts as to constitute fully three-fourths of the mass of the rock.

Chert beds and nodules. A remarkable character is imparted to vertical sections of this rock in the Mendip hills, in several parts of Derbyshire, and the neighbourhood of Clithero, by nodules of chert imbedded in the limestone, often at regular distances, like the flints in chalk. A very striking section of this kind is seen in Vallis Bottom, near Wells. This chert is usually of a dark grey, or even black colour, but occasionally it is white, and in general its colour corresponds to that of the limestone beds which contain it. It rarely contains any organic nucleus, and thus differs from a large proportion of the flint nodules in chalk, with which, in the manner of its production, and in its relations to the calcareous rocks, it seems otherwise very analogous. The cherty layers in green sand and coralline oolite are also analogous instances, and we have hereafter to notice a similar character in a certain portion of the magnesian limestone. Proceeding Northward, as the limestones are divided, these chert nodules are less plentiful, though in Coverdale, in Yorkshire, they abound, and at Glenwhelt, on the Roman wall, shells of the genus *Bellerophon* have been detected in a very dark chert imbedded in the limestone there.

Chert beds. The curious circumstance of conversion, as the miners say, or rather substitution of beds of chert for beds of limestone, generally at the top of the rock, is noticed in most parts of the limestone tract in England and Wales; and very often it happens, as in Westmoreland, that the corals are converted to silicious matter in the midst of a block of limestone. It is probable that the substance resembling rottenstone of Dentdale, Swaledale, and Aldstone Moor, may be occasioned by decomposition of this chert, but Mr. Farey thinks the rottenstone of Derbyshire is owing to a decomposition or change of the shale limestone near the surface. A specimen collected by the author at Aldstone Moor in 1820, which as to substance is a kind of rottenstone, is evidently decomposed chert, and contains several fossils of the limestone series, especially a very small species of trilobites. Similar facts are common in the Yorkshire dales.

Bitumen in solid masses lies very frequently in the beds of the scar limestone, and enters the cavities of productæ, orthocerata, &c.; as at Castleton, and near Clithero. In a liquid as well as solid state it will be noticed under the next division of the carboniferous strata.

Physical geography. The surface of the country which is occupied by this rock in England is remarkably characteristic. Having been exposed to many repeated convulsions, it is thrown up to considerable altitudes, and placed in a great variety of positions favourable for the exhibition of the changes wrought on it by the atmosphere and streams. It is principally to the hardness and comparative durability of this rock, conjoined with its stratification and extensive system of *joints*, that we owe the grand ranges of vertical escarpments, which begird with a perpetual fortification the sides of the dales of Yorkshire and Derbyshire. Often, indeed, the wasting effect of the elements is sufficient to excavate vertical rents and to insulate the great prisms of the rock which, especially in Dovedale and other parts of Derbyshire, give the most romantic features to the valleys, while the same effects upon the high scars in Yorkshire and Westmoreland show like towers and bastions projecting from the wall of rocks or among the green herbage which has spread around them.

Frequently upon broad surfaces of limestone, especially where it alternates with shale, we find ourselves suddenly stopped by a deep vertical pit in the rocks, worked by some little rill, or even by the mere gathering of rains, an effect more frequently observed in the course of streams, which, like the Calder in Cumberland, traverse the ranges of this rock. These "swallow holes," as they are justly called, often serve to mark out uninterruptedly for miles the lines of limestones, whose actual edges may be obscured by the sliding of other matter over them. Swallow holes.

These swallow holes sometimes communicate downwards with internal caverns, which are nowhere so abundant as in the lower or scar limestones. It is to them we must refer the numerous caverns of Mendip hills, in Somersetshire, the rocks of Clifton, the Forest of Dean, the celebrated caverns of Staffordshire and Derbyshire, and those beneath Ingleborough and Penygant, in Yorkshire. Further North, along the Penine chain, where these limestones grow thinner, the caverns become less numerous, and in the same proportion the phenomenon of underground streams is rarely observed. This remarkable phenomenon is evidently dependent on the thickness, as well as on the open joints and absorbent surface of the rock, and examples of the same kind occur in various other thick calcareous strata of England, as the oolites and chalk, as well as in the Jura limestone or oolite of Germany and France. It is to the same causes that we must ascribe the extraordinary strength of the springs which issue as clear as crystal from the openings of this rock: but, being highly charged with carbonate of lime, soon deposit along their channel abundance of tufa. The herbage upon this limestone is usually short, elastic, and nutritious, and of a lovely green, which contrasts strongly with the bluish aspect of the moist surfaces of the shales, and the brown tints of the heathy moorlands of millstone grit.

Flagstone Series.

The shale and grit, or flagstone series above the scar limestones, is called in Derbyshire the limestone shale. It is about 500 feet thick, and consists principally of black or brown rather durable shale, forming a very wet soil, and causing land slips of great extent beneath the millstone grit summits. Mam Tor, the "Shivering Mountain," near Castleton, exhibits these characters very decidedly. The shale, however, is interstratified to a great extent, and with a considerable regularity, with thick rocks of fine-grained micaceous gritstone, of excellent quality for building, and, as we have observed, generally at the bottom of this rock, with good durable micaceous flagstone, very similar to that in the more recent coal strata. Some less regular sandstone beds, called "Cankstone," approach very nearly to the nature of the ganister or calliard rocks of the coal strata. Mr. Farey, who considers these *interpolations* as *anomalies*, calls by the same name the very characteristic beds of black argillaceous limestone which lie in this shale, at Ashford, near Bakewell, and near Ashborne, and produce lime fit for water cement. The frequent contor- In Derbyshire.

Geology. Ch. II.

tions of the limestone and shale are noticed by Mr. Farey as very remarkable. Ironstone balls lie in bands in this shale, a few *impressions of fossil plants* have been collected, and very thin coal seams observed, not worth the expense of the fruitless trials in search of them. Liquid bitumen is mentioned at several points in connection with the limestones in this shale.

In Yorkshire.

This description of the Derbyshire limestone shale would apply with scarcely a varying sentence to the broad argillaceous strata which cover the thick limestones of Craven. The same abundance of shale, occasional interpolations of sandstone, ironstone, and laminated beds of dark limestone, the same traces of coal and liquid bitumen, the same contortions, may be traced in Craven and in Wharfdale. More divided by sandstones and limestones, the same shale is recognised in Pendle Hill, Ingleborough, and Penygant. The locality most remarkable for the abundance of liquid bitumen is at Flasby in Craven, where Mr. Preston has excavated a considerable quantity of the black argillaceous limestone, and found it associated with abundance of nautilus sphericus besides large orthocerata and the curious fossil formerly supposed to be a pleurobranchus. The nautili are generally inverted or have their cavities filled with liquid bitumen, and small solid lumps of the same substance are likewise met with. This, amongst others, is one strong reason for believing that the darkness of colour of these limestones and shales is due to the admixture of carbonaceous matter.

By a recent communication of Sir Philip Egerton and Lord Cole to the Geological Society, we have learned that the lower coal shale, as it has been termed in the Western Irish coal fields, is precisely analogous not only in mineralogical characters, and in its geological position between the mountain limestone and the true coal measures, but also in its organic remains, to the "limestone shale" of Derbyshire and Craven. The same ammonites, the same posidoniæ, (Bronn,) and other characteristic fossils occur in these far separated districts; and in general, so strict is the accordance in all respects, that no Geologist accustomed to the strata of the North of England, could fail to recognise in the mountains above Enniskillen an exact analogy with Ingleborough and Great Whernside.

Penine chain.

In the further continuation Northward of this series of shales, sandstones, and limestones, the limestones, as before observed, thicken, the alternations of sandstone and shale therefore become more frequent and divided, coal seams intervene, and the whole assumes the character of a complicated coal and limestone deposit. It is possible, in tracing the different limestones enumerated in this series, to assign characters of local permanence. Thus the beds most remarkably stored with crinoidal reliquiæ, are those of the "main lime," in Pendle Hill, Ingleborough, Cam Fell, &c.; the black limestone of Whalley, Kirby Lonsdale, and Dent, is almost wholly deprived of them, like the same beds in Derbyshire; productæ abound on the top of the main lime, caryophylliæ are often plentiful in the beds below it, and one thin bed of limestone, at Aldstone Moor, receives, in consequence of the nature of its organic contents, the name of Cockleshell Lime. Chert lies frequently on the top of the main lime, and underset or four fathom lime beneath it, as well as on the top of the little lime or crow lime above it. Slaty sandstone yielding flagstone occurs both in the alternations under the main lime, and in those still lower between the underset and scar limestones. In one or other of these places in the section, flagstones are dug in Swaledale and Yoredale, in Graygarth fell, near Kirby Lonsdale, and Garstang, and it is probable that the flagstones of the North of Derbyshire belong to the same epoch. In some of the very hard sandstones which occur in this series in Swaledale, (like the cankstone of Derbyshire,) stigmariæ and other fossil plants occur, but in general the coal seams are not accompanied by many vegetable remains.

A kind of rottenstone, as before mentioned, occurs in this series in Dentdale and at Aldstone Moor, and probably in many other places is produced from the decomposition of the chert.

The shales of this tract are usually dark, close, and fissile, and traversed by immensely long straight joints ranging North by West, and South by East, East North-East and West South-West, dividing the rock into rhomboidal prisms. They often contain nodules of ironstone. A very remarkably indurated flinty shale, fit for use on the roads, which occurs in Swaledale and Yoredale above the main limestone, is called "Black beds."

The sandstones vary as to fineness of grain, and some of them in their progress through Northumberland assume such a coarseness of aspect, as to be in fact undistinguishable from the "millstone grit" of the next group.

The marine fossil remains are almost wholly confined to the limestones and the cherts which sometimes replace them, but the few vegetable remains belong wholly to the sandstones and to the coal.

Coal field of Midlothian

In the Midlothian coal field in the Counties of Edinburgh, Haddington, and Peebles, Mr. Farey sen., in 1816, ascertained 337 principal alternations of strata between the surface in the town of Fisher Row on the banks of the Frith of Forth, (where the highest of these strata occur,) the commencement of the basaltic rocks forming the general floor and border of this important coal field. These strata lie internally in the form of a lengthened basin or trough, and consist of sandstone, shale, coal, limestone, ironstone, &c. 66 seams of coal, counting the double seams as one; 7 limestones; 72 assemblages of stone and other sinkings; in all 5000 feet in thickness.

Upper Limestone Belt.

The only additional remarks which we shall make on this portion of the strata refer to the remarkable variation of character, by which the limestone in several places is gradually changed to or suddenly replaced by chert. Thus in Swaledale the united thickness of the underset chert and underset lime (the former being uppermost) is nearly constant, but the thickness of each is extremely variable. In like manner in Wharfdale, about Kettlewell, the underset lime just before it expires entirely under Great Whernside, is represented only by hard chert, and the main lime of the same district before it thins out and dies away becomes remarkably cherty, both by the change of whole beds and the introduction of chert nodules. There appears some reason to attribute this effect, in one case, to the operation of a vein, while in others it may, perhaps, be properly viewed as indicating merely the suppression of the calcareous deposit independently of the silicious. It must be owned, however, that the notion of miners, and that first suggested to the Geologist, agree in assigning the

effect in some instances, even independent of dykes or veins, to a real chemical conversion of the nature of the rock since its deposition.

Millstone Grit Series.

Mineral composition.

The difference of composition between the coarse sandstones which abound in this part of the series, and those of finer grain which alternate with the limestones below and the coals above, is rather apparent than essential. That all these sandstones are composed of the broken and triturated ingredients of older crystalline, generally granitic compounds, is evident upon inspection. Their most abundant ingredient, sand, is plainly in the state of minute pebbles, and the size of these grains is sometimes so very small, that their coherent mass assumes almost a crystalline aspect, as, for example, in the Calliard stones. On the other hand, in millstone grit they are of all sizes under an egg, though pieces of greater size than this are sometimes seen. These are evidently quartz pebbles of different kinds, corresponding to the quartz of veins and of granites. Rose quartz also has been observed. The next abundant ingredient is felspar, which is probably present in all these sandstones. In the millstone grit this mineral occurs in *rounded pebbles* whose *internal structure is perfectly crystalline*, like the large rhomboidal crystals in the porphyritic granites. Hence we learn clearly the history of such a sandstone deposit. The materials were derived from crystallized rocks, and were subsequently more or less rolled about and deposited in water. Mica, the third ingredient of granitic rocks, is less abundant in millstone grit, except in certain layers where it is occasionally very plentiful. It is usually of a pale silvery colour and is in very thin fragmentary scales. The decomposition of the felspar leaves a white, soft, unctuous substance, analogous to the kaolin of decomposed granite, and this forms a feeble cement for the grains of sand and mica. Occasionally in millstone grit, as in the other sandstones of the carboniferous system, we find oxidulous iron and some other mineral substances not easily recognised, and in Lancashire, frequently, fragments of shale, coal, &c. Every thing, therefore, concurs to prove the mechanical watery origin of millstone grit, and by consequence of all the other sandstones associated with it, the differences between them being only of degree. In the same manner nearly a gradual series of changes assimilates sandstone and shale, and it is sufficiently proved that the only really chemical aqueous deposit of this whole system is the limestone.

The millstone grit of the Southern coal fields is usually a much harder and more compact and cherty rock than the coarse pebbly strata which bear this name in the North of England. Finally, we must repeat the remark previously made that this series is limited in extent, not being of much importance or really characteristic of a certain period except between the Trent and the Tyne. Through the remainder of Northumberland it is less remarkable than several other equally coarse grit rocks, called crag grits in Mr. Smith's Map of Northumberland, which lie in the limestone series considerably below the upper limestone belt. Excellent building stone is furnished by this rock in Yorkshire, Lancashire, and Derbyshire, and by its representative, the "Farewell Rock" of Dean Forest and South Wales, which have the valuable property of standing great heat, and are therefore employed in certain parts of the iron furnaces.

THE COAL FORMATION (OR COAL MEASURES) consists of alternating strata of sandstone, shale, and coal, with courses of nodular ironstone, layers of bivalve shells, and, in a certain part, argillo-calcareous balls and nodules generally enclosing ammonites, pectens, &c.

None of these strata differ individually in any essential points from the analogous deposits in the millstone grit, or limestone series beneath; their characteristic features are derived from their combination. It is, indeed, generally true, that the sandstones of the coal measures are softer and more argillaceous than those of the series below, that the coal shales are less indurated and less fissile than the "plates" of the limestone group, and the coal generally of better quality. But it is by the *greater abundance* of the coal seams, and by the *absence* of limestone beds that the upper part of the carboniferous system is to be distinguished from the lower. It is, therefore, perfectly conceivable, that cases may occur when the lower or calcareo-carboniferous group may, by the attenuation of its limestones and the thickening of its coals, become so similar to the upper group or true coal measures, that their relative ages can be only determined by collateral evidence. This extreme case has, indeed, hardly yet been observed in any of the known coal districts of the New or Old World, but the approaches to it in Northumberland and Scotland are sufficient to show that the coal measures have no other real difference from the lower parts of the carboniferous system, than the *total* absence of the oceanic deposit of limestone. In many coal fields the reason of this difference is easily determined by the abundance of *fresh-water shells*, beds of shale, and of ironstone, alternating with the coal.

We have seen with what certainty the range of the mountain limestone can be followed through Great Britain, and its detached portions referred to their true place in the series of its beds, and thus Geological parallels be established between the Mendip Hills, Derbyshire, Yorkshire, and Northumberland. The coal measures of Great Britain cover quite as large a surface, and are, perhaps, quite as well identified *in mass*; but the details of the several coal fields are too discordant, to permit many of these parallels to be drawn, without which the *method of variation* by which one such coal field becomes different from another cannot be determined. This is so entirely well known, that often in the *same coal field* the differences are so considerable as to render it difficult to identify the beds of the two extremes. It must be owned, however, that this is partly owing to the confusion of nomenclature amongst the workmen, though principally to the sudden changes of chemical quality to which the coal seams are liable.

The extent of the coal fields of England and Wales may be seen upon Mr. Smith's and Mr. Greenough's Geological Maps; those of Scotland also are sketched upon Mr. Smith's Map; Mr. Griffith's Surveys and Mr. Weaver's observations have contributed much information on the coal measures of Ireland, and many valuable notices in the *Annales des Mines*, *Annales des Sciences Naturelles*, &c., make us acquainted with the same series in France. For the Netherlands the same Journals and the Memoirs of Omalius d'Halloy, and for the German and Transylvanian coal fields the works of

Geology. Ch. II.

Villefosse, Freisleben, Hoffman, Sternberg, and others may be consulted. Mr. Conybeare has given a general view of these foreign coal tracts in the Geology of England and Wales.

English coal fields.

We shall consider the characters of the principal English coal fields in the following order:

1. The great Northern coal fields of Northumberland and Durham, Yorkshire and Derbyshire, and their appendages.

2. The South-Western coal fields of South Wales, Dean Forest, Somersetshire, and Kingswood.

3. The coal fields of North Wales and Shropshire.

4. The central English coal fields.

That the great Northern coal fields of Northumberland and Durham, and of Yorkshire and Derbyshire, were formed under very similar circumstances, and, if never connected towards the borders, were united in the deeper parts of the deposit, will appear from the following comparisons. The Northern and Southern portion of this great tract, though now separated sixty miles, agree in being formed within a belt of coarse pebbly sandstones (millstone grit) associated with thin coals, which overlay the mountain limestone, and in being covered *unconformedly* by the magnesian limestone. Coals of like quality are worked in these coal fields in the same parts of the series, bituminous coals of excellent quality in the lower part, quick-burning coals in the upper part. Ironstone courses are most plentiful in the middle and lower part, where also lie the "muscle bands," of which regular layers have been some time known in the coal field of Yorkshire, and are not without representation in that of Newcastle. This latter analogy is very remarkable, and the occurrence of these muscle bands is almost a peculiar character of the great Northern coal fields.

A comparison of the details of these coal fields would afford an excellent test of the points of analogy, and the extent of variation, which may be expected to occur in neighbouring carboniferous deposits.

The broadest part of the whole tract is between Halifax and Ferrybridge, or rather Went Bridge, in Yorkshire, where the dip is moderate and regularly to the South-East, the stratification not subject to more than usual disturbance, and the greater part of the coal seams worked to supply the wide-spreading industry of the West Riding. The whole coal system of the Country is thus unfolded, all its products are employed, and the ranges of most of the beds perfectly known. In addition it happens fortunately, that not only the millstone grit is remarkably distinct, and the series immediately above it, the lowest part of "the coal field," unusually developed, and rich in organic remains, both animal and vegetable, but the uppermost part of the system beneath the magnesian limestone is also fully exhibited. This is therefore on all accounts the most complete coal field in the Island, and the fittest to serve as a type of comparison for the others.

Yorkshire coal field.

The following mode of classification of the Yorkshire coal seams will be found very natural and convenient, for the several groups of coals here assumed have certain collective characters derived from this combination, and occupy distinguishable ranges of mostly argillaceous country between lines of sandstone hills.

Magnesian limestone unconformedly covers the coal seams.

Upper coals ...	Shales and Badsworth coal. Ackworth rock. Wragby and Sharleston coals.

Red rock of Woolley, Hooton—Roberts, &c.

Middle coals ..	Furnace coals.	Barnsley thick coal.
	Intermediate coals.	Rock of Horbury. Middle coals.
	Ironstone coals.	Silkstone beds. Low Mow and Flockton coals.

Flagstone rock of Woodhouse, Bradford, Elland, Peniston, &c.

Lower coals. ..	Shales and ganister stone. Coals. Shales and ganister stone. Coal. Shales, &c.

Millstone grit lies below the "coal series."

Lower or ganister coal series.

The lowest portion of the Yorkshire coal strata resting upon the millstone grit produces comparatively but a small quantity of coal, and this not in general of a good quality. But no part of the coal field is more curious in its Geological relations, or more worthy of close study by those who desire to penetrate into the history of the production of coal. We may define this lowest coal series very simply by saying, that it is included between the millstone grit beneath and the flagstone rock above, having a thickness of about 120 or 150 yards, and enclosing near the bottom two thin seams of coal, one or both of them workable, and several other layers scattered through its mass too thin to be worth working.

The most regular and continuous of all these coal seams, reaches in a few places the thickness of 27 or 30 inches, but is generally only about 16 inches, and is worked at Yeadon, Rawdon, and Horsforth, near Leeds; at Baildon and Heaton, near Bradford; at Catharine Slack and Swan Banks, near Halifax; at Bull Houses, near Penistone; and at several points West of Sheffield. It would have been impossible to have traced so thin a seam of coal along so extensive a range without some peculiar facilities, some points of reference more distinct than the varying quality of the coal, and the still more irregular fluctuations of the sandstones and shales. This coal seam is covered by a "roof" unlike that of any other coal bed above the mountain limestone in the British Islands; for instead of containing only the remains of plants or fresh-water shells, it is filled with a considerable diversity of *marine shells* belonging to the genera *pecten* and *ammonites*, and in one locality specimens of *orthoceras*. *Posidonia* and scaly fishes have been obtained from certain nodular concretions, called "baum pots," lying in it. The uniform occurrence of these pectens and ammonites, through so wide a range, over one particular thin bed of coal, and in no other part of the coal strata, is one of the most curious phenomena yet observed concerning the distribution of organic remains, and will undoubtedly be found of the highest importance in all inferences concerning the circumstances which attended the production of coal.

In this part of the coal system we may observe, besides the very remarkable layer of marine shells, several occurrences of a peculiarly hard silicious sandstone, called galliard, ganister, seatstone, &c., which, in fact, is the same thing as the crowstone of the mountain limestone series in Swaledale. This stone in some cases forms the floor or sill of the coal, a circumstance never observed in the upper coal strata, amongst which, indeed, galliard never occurs in its true character. Hence this whole group of strata may be appropriately termed the ganister coal series.

The ammonites and pectens which lie above one of the seams of coal, and still more the orthocerata which sometimes accompany them, are remarkably analogous, and perhaps in part identical with fossils of the mountain limestone. The galliard is likewise to be compared with similar stones in the mountain limestone series, and therefore the ganister coal series might be with much propriety associated with the upper mountain limestone series of the Penine chain, or with the millstone grit series of Derbyshire, and thus the flagstone would appear to be the lower limit of the true coal measures. But an examination of the neighbourhood of Halifax has shown another order of phenomena and another set of shells, which connect this same series with the upper or true coal measures. In the upper coal series of Northumberland, Derbyshire, and Yorkshire, are several layers of bivalve shells, commonly referred to the genus unio, from which the fresh-water origin of these coal deposits has been inferred. In the midst of this series of ganister coals two layers of these shells occur, one of them about the middle of the series, considerably *above the pecten coal*, the other near the bottom, and considerably *below that coal*.

No shells of this kind have ever been met with in the mountain limestone group which there is every reason to consider as of decidedly marine origin; not one of all the zoophytic, testaceous, or crustaceous reliquiæ of this limestone has ever been found in the upper coal series. This opposition of zoological characters would appear to be fully explained if the coal deposits were admitted to have been accumulated in fresh water. And this opinion is perhaps generally adopted.

We find then in the lowest coal series, which is placed on the line of transition between the marine and fresh-water deposits, zoological and mineralogical characters common to both. Examined in detail we find these characters not mixed, but alternating in such a manner as if there had been one periodical return of the marine element into its ancient receptacle, after that had been for some time occupied by fresh water and its few inhabitants. The effects of this irruption having as it were worn out, the zoological characters of fresh-water deposits are again manifested at intervals, in the upper system of coal beds, till this series is finally ended, and marine exuviæ reappear in the magnesian limestone.

If, from whatever cause, we could witness the effects of a general irruption of sea-water into a modern lake of great extent and considerable depth, it is probable that the resulting phenomenon would be perfectly analogous in kind to those described above. But this irruption of the ancient ocean into the coal basin of Yorkshire, was probably not produced by any violent convulsion *in that basin*, (for there is no unconformity between the supposed fresh-water and supposed marine deposits,) but by some disturbing causes originating *at a distance*. As the elevation of the Western Alps has probably occasioned the dispersion of boulders in Dauphiné and Provence, and the uplifting of the Scandinavian Alps has been followed by diluvial currents in Germany without much affecting the position of the strata in those Countries, so may the Yorkshire coal district have felt the transient shock of some distant convulsion. The periodical revolution in the nature of the waters which operated the deposition of the lowest coal strata in Yorkshire, bears so remarkable an analogy to some of the phenomena of the marino-lacustrine tertiary deposits, that the same principles will probably serve as a basis for the explanation of both cases.

In both cases we have a *decidedly marine* deposit below, and a *decidedly fresh-water deposit* above; the intermediate ground is not exactly neutral, but sometimes shows gradations from one to the other, and sometimes periodical alternations, accompanied however by so entire a parallelism of strata, that in seeking for the cause of these changes, we are compelled to have recourse to agency at a distance, to the blocking up of the outlet of an estuary, or to irruptions of the sea, arising from subterranean disturbances in a different quarter.

The lower coal series of Yorkshire is terminated above by a thick deposit of sandstone, which is never so coarse as the millstone grit, and generally appears to be more argillaceous. Its degree of consolidation varies according to localities and circumstances of drainage, but there is hardly a single point in its whole range, from the vicinity of Leeds to beyond Sheffield, where the title of flagstone rock is not eminently applicable to it. Along this whole range, by the valley of the Aire to Bradford, over the hills to Halifax and Elland on the Calder, and by Huddersfield and Peniston to Sheffield, it is the grand repository from which the immense demand for Yorkshire flagstone, both within the County and for all the Eastern and Southern coasts, is supplied. In particular situations, especially near the surface, it is often so thinly laminated as to produce good roofing slate, while the deeper parts of the quarries produce capital building stone. This diversity of qualities is consistent with great simplicity in structure. It is a finely laminated stone, having its beds in general very parallel, and thus, according as the whole mass of a bed is employed, or as it is split into portions or resolved into its component plates by the action of natural causes, wallstone, flagstone, and slate result. The micaceous surfaces of every common flagstone immediately disclose to us the cause of its natural partings; and further examination shows the whole thickness to be divided by other layers of mica into a number of parallel plates, which sometimes separate by the mere influence of the air, but generally, after being once dried, cohere together with considerable force. In this case it is difficult to say what technical use should be made of the term *strata*, which may with equal verbal accuracy be applied to the micaceous laminæ, or the plates of slate or flagstone to the beds of the rock singly, or the whole united mass of sandstone layers. In Mr. Smith's nomenclature the whole flagstone rock is one stratum. However this may be determined, there can be no doubt that even the least and thinnest of the micaceous layers owes its origin to a particular operation of water, and required the intervention of a certain interval of time, to permit the separation of the grains of sand and the scales of mica.

Flagstone rock.

It has been said above that the micaceous laminæ, plates of flagstone and beds of the rock, were all parallel. This is usually and very exactly the case, but in certain places while the beds and flagstones, which are only *lesser beds*, are parallel to one another, the *micaceous* layers which make up the mass of the beds, *form considerable angles with the plane of their surfaces*.

Thus in plate i. fig. 2 the upper part of the diagram shows all the partings parallel; and this is the ordinary case of the flagstone rock, but in the lower part of the diagram the micaceous laminæ are inclined to the other surfaces of parting.

Such flagstones have generally a rough or ragged surface, and are much liable to scale off in irregular "shells," which disfigure the beauty of the stone. This oblique lamination of the mica strongly reminds us of the "false bedding" of millstone grit, and of the shelly beds of oolite, which probably were formed in slightly agitated water.

The surface of the rougher flagstone beds is also liable to other peculiarities, as waves or undulations, like the ripple marks on a sandy shore, little hard knobs on one face corresponding to depressions on another, and sometimes a vermicular marking, which more than any thing else resembles the arrangement which semi-fluid matter assumes on smooth surfaces of stone, when these, after having been laid together, are forcibly pulled asunder.

The micaceous layers are not unfrequently coloured with a mixture of carbonaceous particles.

Vegetable remains lie in this rock in many places, and in considerable plenty. Equisetaceous plants in particular are abundant in it about Leeds, accompanied by trihedral fruits. Lepidodendra, sigillaria, &c. occur in it less plentifully.

In general, what is said of the accidents of structure of the flagstone rock of the Yorkshire coal fields applies to the laminated sandstone rocks of the mountain limestone, and even to the analogous but more recent layers in the oolitic coal system on the coast of Yorkshire.

Middle coal ies.

This is the most valuable part of the Yorkshire coal field, and includes as many as ten workable seams of coal, of various quality, with several layers of ironstone bands, one of them full of fresh-water shells. The flagstone rocks define the series below, and the coarse, often iron-stained sandstones of Newmiller Dam, Woolley Edge, and Rawmarsh form its upper boundary.

It may be convenient to divide this great group into three portions, thus:—

	Red rock of Woolley Edge.
	Furnace coals of Barnsley, &c., including the eight or ten feet seam.
	Rock of Horbury and Wentworth House.
	Swift-burning coals of Middleton, Dewsbury, &c., with bands of "muscles."
Ironstone coals.	Bituminous coals of Silkstone, Low Moor, and Flockton.
	Flagstone rocks beneath.

Upper coal series.

Upon the coarse rocks of Woolley Edge lies the upper series of coal measures in Yorkshire, which exhibits alternations of sandstones and shales very much like those of the middle and lower groups, but without the layers of muscles, and generally without the presence of productive ironstone bands. The reliquiæ of plants are more rare in these strata, and the coal is of inferior quality, more earthy and less bituminous. Two considerable seams of coal near the bottom, worked at Wragby, Sharleston, &c., and one or two thinner seams nearer the top of this series, appear to be the last of the formation, and are unconformably covered, as are all the others in their turn, by the magnesian limestone, against which deposit the line of separation is hard and distinct.

Comparisons with other coal fields.

We are now in a condition to institute a comparison between the results of observation on the strata of the Yorkshire coal fields, and those which had been drawn from similar researches on the other coal districts of Britain and the Continent. For this purpose it will be of little use to take into account the number or thickness, or chemical quality of the beds of coal, since these characters, however important locally, are too variable to guide us across even the whole extent of a single coal basin, and vanish altogether upon distant points. We must, therefore, restrict ourselves to the most general divisions of the carboniferous series, and compare the coal fields with reference to the strata which separate the coal from the mountain limestone beneath, the occurrence of bands of ironstone and muscle-shells, the nature of the rocks and shales, and the distribution of organic remains.

The great Northern coal fields.

The characters of the Yorkshire coal fields are recognised in their continuation Southward through Derbyshire and Nottinghamshire. The same ranges of millstone grit and shales lie beneath, similar rocks of hard ganister lie in the lower part, with a similar belt of useful flagstone. The lower part of the series contains the most bituminous coals, and the most abundant course of ironstone, some of which contain fresh-water shells, and the upper parts yield similar swift-burning thick coals.

The Lancashire and Cheshire coal fields are certainly portions of this great Northern system, separated in consequence of the subsequent uplifting of the mountain range of the Penine Alps. The same *ganister* and flagstone occurs near Stayley Bridge, resting in the same order of succession upon the same millstone grits, and though the broken condition of the coal fields on the West of the summit ridge scarcely allows of the same accurate delineation of the courses of the coal beds, enough is already known to justify the reunion of the coal-deposits on both sides of the Penine Alps.

Notwithstanding the great interval in the superficial range of the coal strata between Aberford and Cockfield Fell, the series in the Durham and Newcastle coal fields is very analogous to that of Yorkshire.

But hitherto, no layer of marine shells has been noticed in the lower part of the Newcastle coal fields, and, therefore, the inference of alternate inundations of the sea and fresh water cannot be applied to this coal field, though the general conclusion of marine deposits below, and freshwater deposits above, remains unimpaired.

Fresh-water shells, accompanied by nodular ironstones, and numerous reliquiæ of equisetiform and filicoid plants occur *without limestone* beds in the coal fields of Clackmannanshire, Falkirk, and St. Andrew's, but most of the Scotch coal fields, like that of the North and West of Northumberland, are formed by a developement of the carboniferous limestone group of Yorkshire and Durham, and contain marine shells.

Great South Wales coal field.

The immense coal basin of South Wales (which is, in fact, as Mr. Conybeare has shown, divided into two parallel basins by a longitudinal axis of elevation,) presents so many features in common with the detached coal tracts of Dean Forest, Kingswood, and the valleys of Somersetshire, that for our present purpose we may conveniently group them together.

The total thickness of the coal strata is very great, for in the deepest part of the basin near Neath, the lowest strata of coal are nearly 700 fathoms below the outcrop of some of the superior strata in the more hilly parts of this district. There are (according to Mr. Martin) 23 beds of workable coal, making altogether 95 feet, 12 of them from 3 to 9 feet thick, 11 from 18 inches to 3 feet; besides numerous other beds from 6 to 18 inches thick.

The coal on the North-Eastern side of the basin is of a coking quality, excellent for the iron manufacture; on the North-Western it contains little or no bitumen,

Geology. Ch. II.

being what is called stone coal or culm; on the South side, from Pontipool to Caermarthen Bay, it is of a bituminous or binding quality. The cause of these extreme differences in the quality of the coal is not known, and, indeed, the subject of the varying quality of a coal bed has never yet been adequately investigated. Many analogous though less striking examples are familiar to every coal-worker of sufficient observation and experience.

The numerous excavations along the Northern border of the South Wales coal district, for the purposes of the iron manufacture, present us with a complete section of the middle and lower parts of the coal measures, the limestone series beneath, and the general base of old red sandstone.

The lowest part of the coal measures consists of alternations of sandstone and shale, without coal; the lowest bed (in the place of millstone grit) being a conglomerate sandstone. Above this series, two or three thin seams of coal occur, and these are followed by an argillaceous series, containing many thick and valuable beds of coal, and sixteen layers of ironstone in thin beds and nodules. Whether the ironstone nodules contain shells has not (it is believed) been stated, but the general analogy of arrangement of the coals and ironstones to that which has been described in the Northern coal fields, will be immediately obvious.

It appears that the upper part of the coal strata is characterised by the predominance of coarse sandstone with carbonaceous specks, like that called Penant in Somersetshire, and that a considerable thickness of such rocks intervenes between the upper and lower coal seams.

This sandstone is occasionally highly micaceous and fissile, and yields very good flagstone and even roofing slate.

The coal strata of this entirely insulated coal field rest occasionally upon a coarse sandstone like millstone grit, but the general floor is mountain limestone, which contains a layer of oxide of iron, in such plenty as to feed the iron furnaces. The coal seams, seventeen in number, contain about thirty-seven feet in thickness of clear coal, which is mostly bituminous and swift-burning, but in the lower seams partakes more of a coking quality. The ironstone nodules which lie in the shales are of little importance; the sandstones are mostly in the lower part of the section.

The neighbouring coal field of Newent rests on transition strata along the Southern and Western edges, and on old red sandstone along the North-Western. (*Geological Proceedings*, 1833.)

The broken coal deposits of South Gloucestershire and Somersetshire agree in being begirt by an irregular belt of mountain limestone and old red sandstone, and occasional patches of sandstones occupying the place of millstone grit. The irregular undulations of the strata in this district, and their concealment through extensive tracts by overlying deposits, present formidable obstacles to the attempt to trace the series of beds which constitute this coal field.

Mr. Conybeare supposes that it may contain as many as fifty or sixty coal seams, most of them very thin, hardly any of them exceeding one yard, and, therefore, unless of good quality, in a country at some distance from more productive collieries, and aided by the improvements of modern machinery, scarcely capable of being worked to profit.

As in the South Wales coal field, shale predominates in the lower, and the Penant grit rock in the middle part of the series: the shale beds frequently contain beautiful impressions of ferns and muscle-shells. (*Geology of England and Wales.*)

The Somersetshire coal fields have been admirably illustrated by Dr. Buckland and the Rev. Wm. Conybeare. (*Geological Transactions.*)

Flintshire.

The well-connected coal basin of Flintshire, in the basis of which the estuary of the Dee is formed, extends from North to South somewhat more than 30 miles, from Llanassa to near Oswestry in Shropshire, forming an exterior belt coextensive with the range of the mountain limestone from the North of the Clwyd; where that limestone is partially interrupted by the mountain of Selattyn, the coal shales rest immediately on the transition slate of that mountain. The coal strata dip generally Eastward, and form in the Northern part a trough beneath the estuary of the Dee, and rise again on the Eastern side of that estuary in the district called Wirral, from whence, sinking again beneath the red sandstone, along the course of the Mersey, they may possibly be prolonged to the South Lancashire coal beds, near Prescot.

Plain of Shrewsbury.

This coal basin in Flintshire commences with beds of shale and sandstone, answering in position and character to the shale and millstone grit of Derbyshire. The coal is of various thickness from three-quarters to five yards, and consists of the common cannel and peacock varieties. (*Geology of England and Wales.*)

The broken patches of coal strata which lie on the South of the Vale of Severn near Shrewsbury, are arranged according to the irregular positions of the transition rocks, which in the Stipperstones, Longmynd, Wenlock Edge, the Wrekin, Caer Caradoc, &c., extend themselves in a curve far to the East of the great body of the slate rocks. The true relations of the coal strata to the transition ranges, between whose projections they are enclosed, have recently been examined by Mr. Murchison, and connected with general views of the dislocations along the line of the upper slate formations. It appears that the carboniferous strata repose on the edges of the slates, and dip towards a common centre under the new red sandstone. At Pitchford the whole carboniferous series is represented by a bituminous breccia, of a few feet in thickness. Three thin beds of coal are, for the most part, observable, and the deposit is distinguished by an included band of limestone similar in mineral aspect to the lacustrine limestones of Central France, and containing minute planorbes very similar to those mentioned above from the middle coal seams of Yorkshire and Northumberland. (*Geological Proceedings*, 1833.)

Coalbrook Dale.

On the East side of the transition ranges of the Wrekin and Wenlock Edge lies the coal field of Coalbrook Dale, which contains at the bottom a sandstone called the little flint, of which the lower part abounds in pebbles, and is, in fact, a millstone grit. The ironstones, which lie in fives or six layers, are balls or broad flat masses, like those in Yorkshire, &c. and contain abundance of the same vegetable impressions, and a few shells; those which we have examined (belonging to the marine genera orbicula, conularia, ammonites) indicate the propriety of an inquiry into the *distribution of the molluscous remains* for comparison with the results of this investigation in Yorkshire.

The coal beds are mostly thin; the ten uppermost

Geology. Ch. II.

are too sulphureous for other uses than lime-burning, and are called stinkers; twelve beds of good coal, in all twenty-five feet thick, the thickest being five feet, succeed, and the lowest bed of the whole formation, eight inches thick, is sulphureous. The best coal of this coal field usually presents a mixture of slate coal and pitch coal, rarely of cannel coal; none of it possesses the property of coking.

The sandstones of this coal tract are usually fine-grained and micaceous, and speckled with fragments of coal; but some of them are coarse-grained, and two remarkably so. The sandstones generally contain vegetable impressions, but never form the roof of the coal, which is invariably shale. Two beds of coarse sandstone, fifteen and a half feet in thickness, are entirely penetrated by petroleum, which flows out perpetually in the *tar spring* at Coalport. This bitumen is likewise found in the basses or indurated slate clay. These details are chiefly derived from observations at Madely colliery, where a pit, sunk to the depth of 729 feet, passes through all the strata, eighty-six in number, which constitute the coal formation.

This coal field rests at Steeraway, and near Little Wenlock, on a thin band of limestone, which Mr. Murchison has recently proved by its fossils to be mountain limestone, whilst in the contiguous extension of this field, the carboniferous strata overlie, *unconformably*, various members of the transition series, with one of which, the transition limestone of Wenlock Edge, they are brought into *conformable* apposition at Lincoln hill.

Clee Hills, &c.

The divided coal-basin of the Clee Hills is elevated upon the mountain limestone and old red sandstone of Corvedale, and contains several seams of coal and layers of ironstone, much confused in their arrangement by interpositions of basaltic dykes and overlying masses, and resting below on a hard conglomerate sandstone. This interesting country has been recently examined by Mr. Murchison. On three sides of the Brown Clee Hill, the coal strata rest on old red sandstone, which to the West is a coarse conglomerate; but on the fourth or South-Eastern side, there is interposed between the old red and the lower coal grits, a thin zone of mountain limestone. (*Geological Proceedings*, 1833.)

Trap rocks confuse the arrangement of the coal strata in the whole space between Corvedale and the Severn, which includes the narrow coal field of Billingsley and Burdley, which has also attracted the labours of the same Geologist.

Central coal fields.

The double coal field which surrounds Ashby de la Zouch is based on mountain limestone, which, like some portions of that of Derbyshire, contains abundance of magnesia; there is, however, no particular correspondence to be remarked in other respects; no millstone grit has been recognised, no flagstone, nor conchiferous ironstone. Amongst the seams of coal is one of the variety called cannel, and another from seventeen to twenty-one feet in thickness. (*Geology of England and Wales.*)

The strata of the Warwickshire coal field are based upon a compact cherty sandstone, called by Mr. Conybeare "millstone grit," but no limestone appears round the escarpment of this narrow coal tract. The seams of coal are liable to great changes of thickness in consequence of the occasional attenuation of the interposed strata of shales.

The coal field of Dudley, Bilston, and Cannock Chase agrees in part with that of Coalbrook Dale, but differs from all the others by the character of the subjacent limestone, for this is generally admitted to belong to the transition system. The coal measures are supposed by modern writers to be unconformed to the limestone, but their dips correspond in direction though not in degree. The limestone is uplifted into a saddle-shaped or anticlinal ridge; the coal strata rest upon its slopes, and are covered by the new red sandstone formation.

There is no millstone grit, nor any flagstone, and (as usually among the central coal basins) the strata are mostly argillaceous. Ironstone courses occur in several parts of the series, but the only valuable ones are near the bottom. The seams of coal are numerous, but only the lower ones are workable.* They are of various thicknesses from two to ten yards, or even fifteen yards.

It is not, however, to be supposed that these enormously thick seams are single beds of coal; they are in fact composed of several beds locally accumulated together, with certain partings, which in other places swell out into considerable thicknesses of shale. Thus the upper part of the ten-yard coal separates from the rest of the beds, and under the title of the "flying reed," becomes a totally distinct bed in the Northern part of the coal tract.

Ireland.

The coal fields of Ireland occupy very large tracts in the centre of that country, and are upon the whole very analogous in general mineral characters and organic contents to those of England. The same absence of limestone, the same kind of succession of sandstones and shales is remarked in them. Carbonaceous or stone coal, like that of South Wales, abounds in the Leinster and Munster districts; bituminous coal in Connaught and Ulster. The Munster coal district is stated by Mr. Griffith to be of greater extent than any English coal field. In this tract (County of Cork) Mr. Weaver supposes certain anthracitic beds to be interposed in greywacke, and to be subject to all its flexures, but certainly the greater part of the coals of Cork and Limerick are of the same age as the English coals. At Ballycastle the coal is found in connection with basalt. (See Conybeare, *Geology of England and Wales.*)

General View of Circumstances under which the Coal Beds were deposited.

I. Few subjects in Geology have been examined under more various points of view than the question of the origin of coal, and the circumstances under which it was deposited. We may wonder at the philosophical blindness which would permit in the last century protracted disputes concerning the vegetable origin of coal, when so many thousand plants converted into that substance were found in the shales and sandstones of every coal district. But in those days this kind of evidence was so little understood, that the inimitable impressions of ferns and other plants from which we are now accustomed to reason concerning the climate and other conditions of the ancient world, were not even admitted to be reliquiæ of the vegetable kingdom.

There is no necessity to enlarge upon the proofs of the origin of coal from vegetables, drawn from an examination of its chemical constitution as compared with vegetable products, and the composition of the ligneous parts of plants, and from the unanswerable identity of the carbonaceous substance, into which a vast multitude of

Geology. Ch. II.

fossil plants have been converted. The chemical constitution of this carbonaceous product of the individual vegetables, is exactly analogous to the chemical constitution of coal; and it is quite probable that hereafter the reason of the variations to which both are subject, whether dependent on the original nature of the plant or produced by subsequent operations, will be as apparent as that of the general agreement arising from a common vegetable origin. (For some remarks on a part of this subject see ch. i. p. 547.)

II. Admitting then the vegetable origin of coal, the next question relates to the situation where the plants grew from which the vast mass of the coal seams was derived.

Many of the plants accompanying coal are of unknown types, and some are too imperfect to permit any botanical deductions; but the researches of Naturalists have nevertheless been successful in determining some general characters of this ancient flora.

The greater number of these plants were decidedly terrestrial.

They appear to be most analogous to tropical tribes of vascular, cryptogamic, and coniferous plants.

They grew then on the land, and it is probable from M. Brongniart's researches, that this land was in a high degree subject to heat and moisture, more so than perhaps even the coasts and islands of tropical seas, to the flora of which situations the coal plants present most remarkable general approximations. (See p. 603.)

III. We may now venture upon the main part of the inquiry which relates to the origin of coal, *viz.* whether the plants from which coal was produced *grew in their present situations*, and were there submerged and buried beneath marine or fluviatile deposits, or were swept down to their present repositories *from distant situations* by land floods and other causes. To guide us in this inquiry the following data may be premised:

1. The *generally uniform*, or *gradually varying*, thickness of the several coal seams over a very large area.

2. The broken and fragmentary condition and confused intermixture of the plants which accompany coal strata, and their being generally *without roots*.

3. The occurrence of the *same species* of plants in shales, ironstones, and sandstones.

4. The occasional vertical position of *broken stems* of large trees.

5. The *parallelism* or conformity of the several beds of coal.

6. The extreme differences in the thickness of the several seams, and the occurrence of many *very thin plates of coal* through many of the coal shales.

Peat bogs

De Luc and several eminent Geologists, and lately M. Adolphe Brongniart, have supposed coal beds to have been originally a sort of peat bogs, or masses of vegetable reliquiæ accumulated round the place of their growth, upon which other vegetables grew, and that subsequently these tracts of country during some extensive convulsions subsided below their former level, and were covered by various mechanical deposits. This hypothesis seems to have been suggested by the seeming analogy in some respects between the chemical changes which have happened to the vegetable matter of peat bogs and of coal, by the occurrence of stems of plants vertically in the coal strata, and by the supposed difficulty of otherwise explaining the acknowledged regularity of the coal beds.

These circumstances may appear to favour the hypothesis of De Luc, but they cannot make us overlook very serious objections to it.

The formation of *peat bogs* is, as far as we know, not of the kind here supposed. It is not by fragments of trees and herbaceous plants accumulated round the place of their growth, but of a variety of successively dying mosses and other moisture-loving plants that the peat bogs *grow up* to the extent which they occupy on the high cold hills of the North of England.

Subterranean forests.

There is, however, another kind of vegetable accumulation which may be thought to throw more light on the origin of coal. The *turf or peat moors*, as they are called in the North of England, which occur in low ground toward the estuaries of rivers, and along the margin of the sea, in many parts of England, contain a mass of vegetable matter, composed of mosses and other humid plants, roots of ling, &c. and envelope trunks of trees, sometimes prostrated in particular directions, apparently cut by art or decayed by time. In some places are oak, in others birch or fir, according, as Mr. William Smith has observed, to the nature of the soil below, which is sand, marl, or clay. With them often lie the remains of terrestrial quadrupeds, land shells, &c.

The marls sometimes contain fresh-water shells, but never marine exuviæ. In most places these accumulations of vegetable reliquiæ are below the level of the sea, and covered by *various alternations* of mechanical deposits, sands, and clays brought down by the rivers or deposited by the tide.

These phenomena appear to admit of an easy explanation, if we allow that the relative level of the sea and land has been locally subject to variation, and thus the drainage of the country deranged.

The greatest part of the vegetable mass grew in its present situation; it was a humid forest where the leaves and branches of the trees, mingling with the herbaceous covering at their base, formed an extensive carbonaceous mass, which enveloped the trees when they fell by any great violence of wind or flood, perished by natural decay near the base, or yielded to the axe of the old inhabitant. In cases where the situation was elevated, or otherwise removed from the action of the tide, the ancient forest has been sometimes converted to a lake, or overwhelmed with the ruins brought by a land-flood. Along the side of great rivers, where the level was permanently below the floods or tides, many successions of sandy and argillaceous deposits have taken place, and sometimes a second accumulation of vegetables; and thus the whole alluvial *sediment and subterranean forest* resembles in some important respects the alternations of earthy deposits and carbonaceous layers which compose the ancient coal strata.

Lake deposits.

We have, however, not yet exhausted the heads of the subject of the agglomeration of vegetable reliquiæ. In many situations in England, as in Holderness, (*Geology of Yorkshire*,) they have been swept down from the land, and accumulated on the beds of lakes in a pretty regular stratum of partly decomposed leaves and herbs, with branches of hazel bushes, nuts, &c. and fragments of larger trees. Over them the lake has since diffused, in regular layers, the sediment brought into it by the streams and floods, with the shells which lived in the waters.

River deposits.

The Mississippi and other great rivers of the World whose banks are clothed with immense primeval forests,

where from age to age the trees as they fall are rolled away by the periodical inundations, deposit in their wide mouths *alternate* and repeated layers of vegetable and earthy matter, and thus present us with another analogy to the coal strata more exact in detail than any of the preceding, and more justly comparable in extent of effect.

To what distance in the sea trees may be rolled by the mighty continental floods, those who have been accustomed only to contemplate the trifling streams of England, can have no proper idea; but the navigator who at the distance of two or three hundred miles recognises in the Atlantic the last effort of the current of the Amazons, or in the Bay of Bengal observes the immense accumulations of earthy sediment transported by the gentler waters of the Ganges, will readily admit that the estuary deposits from such rivers may exceed the area of the most extensive of our coal basins. (See Lyell's *Geology*.)

Effects of higher temperature.

If we are right in the inference that the ancient flora which lies buried in our coal tracts was the growth of even more than tropical heat and moisture, we may readily conceive how these circumstances, joined to the certain fact that the land was then of far more limited surface, would also explain the *greater amount* of both the organic and inorganic depositions from the ancient drainage of the earth. For a higher temperature of the air and earth, accompanied by more abundant moisture, would naturally be followed by more luxuriant vegetation, more abundant precipitation of rain, greater and stronger rivers, and more violently excited floods. As the rich vegetation and atmospheric storms and destructive floods of the tropical region exceed those of our colder latitudes, so would the effects of the ancient floods in still hotter climates surpass the most powerful results of the present combination of agents.

It is possible that the effect may have been heightened by some essential difference in the constitution of the atmosphere; (M. Brongniart supposes by a large proportion of carbonic acid;) but without at present entering these fields of hypothesis, the botanic characters of the fossil flora appear to warrant the conclusion above stated.

From this short review of the operations now in progress, by which a part of the decayed vegetable covering of the earth is accumulated in peat bogs, lakes, estuaries, and the sea, we perceive clearly that if the production of coal be not now actually in progress in certain situations, deposits of carbonaceous substances happen under circumstances which will greatly contribute to correct and simplify our notions of the origin of that combustible.

Coal formed in various situations.

Until all the circumstances which characterise the different coal basins have been very fully investigated, it will be hazardous to decide *generally* against any hypothesis advanced to explain the deposition of coal, which proceeds upon observation of the accumulations of vegetable matter now in operation. It may hereafter appear that the vegetables of some coal basins grew where their remains are now carbonized, according to M. Brongniart's notion; that other coal beds arose from trees and plants, swept down from the land into fresh-water lakes; that others were formed in estuaries alternately traversed by floods from the land and tides from the sea; and that some were transported far into the deep and tranquil ocean.

But all the weight of observation yet made is decidedly in favour of the opinion that the *greater portion of all the carbonaceous* deposits were swept down from the places where they grew on the land, to ancient lakes, estuaries, and seas; and, indeed, it is perhaps not yet made *probable* that any continuous bed of coal has been produced otherwise.

Generally not where the plants grew.

For De Luc's notion of the plants growing in the very spot where they have been converted to coal seems altogether inapplicable to cases where many layers of coal alternate with many of sandstones, shales, ironstones, &c. For this could only have happened, according to that notion, in consequence of at least as many subsidences and subsequent elevations of the same tract of strata, as there are coal seams in it; and when in addition we take into account the perfect parallelism of the strata indicating no disturbance, the thin laminæ of coal which sometimes occur in the shales, the local divisions of the seams of coal, and the quantity of land plants lodged in the separating strata, we shall be compelled to limit to very few cases an hypothesis which involves such gratuitous difficulties.

1. On the contrary, these very circumstances are exactly such as must necessarily be occasioned by the effects of periodical floods operating through a long succession of time upon a well-wooded country. They would transport at intervals vast quantities of vegetable and mineral matter into the lowest receptacles of water. There the mingled mass would be *sorted by the waters*, according to bulk and specific gravity, as we observe every day in lakes and on the sea-shore, an effect which most probably would be much heightened by the unequal velocity with which masses of such unequal bulk and gravity would be originally transported by the current. They would be deposited in distinct layers, of which the *most regular and uniform* would be the layers of plants, because these are more different both as to bulk and specific gravity from the other materials brought along by the stream, than are these materials among one another; a fact *remarkably conformable to observation*.

2. But though the greater mass of the plants would be thus separated from the earthy sediment, there would probably be some portion unavoidably entangled therewith and deposited with them, and thus the sandstones and shale are found to contain in confused admixture a considerable number of plants.

3. The trees thus transported by the floods might for the most part not have been uprooted; they would also in their course be broken and mutilated, and mostly deprived of branches and leaves, exactly as we find them in the coal strata.

4. In the various eddies of the waters under which the sediment fell, some trees might be reared upright, and others might and indeed would float with the heaviest end downward, and be kept in that posture by a sudden and great accumulation of sediment, and thus we seem to have a natural explanation of the occasionally vertical position of trunks of sigillariæ, and equisetaceæ in sandstone. In shale deposited more tranquilly, this fact has never or most rarely been noticed.

5. Successive operations of this kind would equalize the results over a large area, and produce a remarkably general parallelism of strata in the *same basin*.

6. According to the condition of the currents, the accumulations at any given time, or for any period, might be in one part wholly vegetable, in another wholly earthy, or of alternate quality, and thus the occasional

deadness of a part of a coal tract usually productive, the division of a coal seam into its constituent portions, and the partings of a coal bed appear all perfectly natural consequences of the same simple cause.

7. It is probable that in lakes which receive floods overcharged with sediment, and which in consequence are frequently muddy, few kinds of mollusca, or fishes, or other animals would live, and that the molluscous remains would be such only as belonged to bivalves, like unio and anodon, or univalves, like paludina, which never come to the surface for respiration, but remain at the bottom of the waters. The shells found in coal tracts, supposed to be of fresh-water origin, are principally uniones and anodonta.

8. It is also probable, for the same reason, that only a small number of the animals or plants actually existing in the sea at any one time would be found within the area of a very muddy estuary, and thus we see the reason why the coal basins which contain no fresh-water shells, and are from other circumstances presumed to be of marine origin, are generally devoid of animal remains, except in the calcareous layers or nodules which may occur in them. These calcareous deposits evidently mark periods during which the chemical precipitations from the sea were little or not at all troubled by the mechanical aggregations from the floods of the land.

9. As many basins of fresh water, estuaries, or seas, as received the vegetables and sediment brought down by the floods, so many distinct series of carbonaceous and argillo-arenaceous deposits would be produced;—there would be no *particular agreement* between them in the number, thickness, and quality and arrangement of the coal seams, rocks, or shales, or ironstone, but a *general agreement*, depending on the common physical conditions of the region. But in the *same basin*, even over very large areas, there would frequently occur *particular agreements*, in many respects; coals of particular quality, rocks of certain kinds, beds of ironstone, and layers of shells, may be traced over large tracts and assigned to definite places in the general section.

Convulsive Movements of the Carboniferous System.

Nothing appears more clear in Geology than that the same parts of the Globe have been alternately subject to gradual alteration, through the slow and equal action of the ordinary system of Nature, and to sudden extreme changes induced by the shorter dominion of violent disturbing forces.

The preceding descriptions sufficiently show how regular was the action of the causes which permitted the immense accumulations of chemical deposits, earthy sediment and vegetable reliquiæ, on the beds of ancient lakes or estuaries, and for how long a period this process continued, the prodigious number of alternations in the deposits sufficiently attests. It was, indeed, compared to the present state of things, a period of remarkable excitement as to the vigour of vegetation, and perhaps also as to the abundance and force of inundations; but the parts of this series, compared with one another and with analogous strata of different ages, furnish proof that the whole was the result of what may be termed the then ordinary course of natural operations.

Extent of these disturbances. But this long period appears to have come suddenly to an end, and the characteristic regularity of its deposits to have been interrupted by a general eruption of disturbing forces which have left the traces of their power and extent in all the coal fields of Europe and America. As after the deposit of the slates violent dislocations happened and were succeeded by the old red conglomerate, so after the deposit of the coal, similar and equally extensive interruptions of the planes and course of strata were followed by the analogous deposit of new red sandstone. In the course of these operations, the whole thickness of at least the stratified mass of the crust of the Globe appears to have been broken in many directions, and the divided portions raised or depressed a few inches, many yards, or hundreds of fathoms from their former level, and placed in new situations, with various angles of inclination to the horizon and in various directions. Scarcely a mine or colliery is worked in strata of this era in any part of the World which is not crossed by several faults or dislocations of this nature, and it is always found that they divide and displace in the same direction the whole series of the strata to the greatest depths which man has reached.

That these dislocations happened after the complete deposit and induration of the coal strata is evident; that they followed almost immediately, and happened nearly at the same period of time, in almost all the coal tracts, appears certain from the general fact, that the disturbances of the coal seams rarely extend into the newer strata of magnesian lime and red sandstone. There was, therefore, a general disturbing agency employed to break up the consolidated planes of the carboniferous strata; and from the occasional filling of the dislocations with basalt, various crystallized minerals, and other igneous products, no doubt can remain that the principal agent was that general source of heat which is included within our Planet, and which finds vent for its energies in different places at different times.

To particularize all, or even the most remarkable of the faults of the carboniferous systems of different Countries, and to notice all the variations of their appearance, would be entirely foreign to the intention of this treatise; such details must be sought in special descriptions of the several mining districts and coal fields. But we shall notice some of the most predominant of these dislocations, which appear to have caused the most extensive alterations in the level of the strata, and to have been most efficient in uplifting particular ranges of land, and giving new boundaries to the Ocean.

That most of the carboniferous deposits were originally limited in area, has been already stated, and therefore we must be cautious not to infer the *violent* separation of two coal tracts from the mere fact of their disunion, without reference to the connecting inferior strata. Thus the coal fields of the Forth and the Clyde were probably limited by the previous elevation of the ranges of the Grampians and the Lammermuir, and though presenting strong analogies with the Northern coal fields of Northumberland, there is no reason to believe that they were ever joined to them. Keeping this in view, and guided by a knowledge of the *characteristic points* of the several systems of strata, we shall be able with more or less facility to determine the amount of the disturbance of position induced on any given coal tract, and thus to restore in imagination the original condition of the strata. The separation of the great coal fields of Northumberland and Durham on the *one* hand from those of Yorkshire and Derbyshire on the other, appears to have been caused by a general elevation in an Eastern and Western range of the whole of the tract intervening between Wharfdale and Teesdale.

Geology. Ch. II.

In consequence of this and the *waste of the elevated surface*, it happens that while the lower parts of the carboniferous system are connected, the upper parts are entirely divided, and the magnesian limestone lies level on the coal of Durham and millstone grit of Nidsdale, and again covers coal in Airedale.

Penine chain.

Again, all of the great Northern carboniferous tracts are arranged with relation to an almost continuous Northern and Southern axis of elevation, from the mountains round the source of the South Tyne to Ingleborough, through Bolland forest, by Pendle hill and the Western border of Yorkshire, to the limestone district of Derbyshire, while the particular fields of Hartley Burn and Black Burton depend upon two cross lines of *dislocation* or fault, the former passing Eastward under the name of the main, or 90 fathom dyke, from near Brampton to the sea-side near Tynemouth, and depressing the strata to the North, while the latter ranges East South-East by a remarkable line of slate rocks from Kirby Lonsdale to near Grassington, and throws down to the South. The carboniferous rocks which surround the Lake mountains have certainly been affected by elevations subsequent to those which in that district followed the deposit of slate, and anterior to the deposit of the superincumbent red sandstone.

A large proportion of the mineral veins which divide the carboniferous limestone series of Aldstone Moor, and the mining dales of Durham and Yorkshire, range East and West, and may be reasonably viewed as lateral fissures proceeding from the main axis of elevation which they join nearly at right angles. The same direction at right angles to the continuation of the same principal axis of elevation is recognised in the veins of Derbyshire, some of which range to the North-East and others to the South-East, and, though with considerable variations, appears to prevail amongst the numerous faults or slips of the coal field of Yorkshire.

The great Northern and Southern axis of elevation of the carboniferous series in Derbyshire is broken across on the North, near Castleton, and appears to be terminated on the South, near Bradbourn, by great cross faults; and the whole of the coal measures of Nottinghamshire and Derbyshire, on the East, and of Staffordshire on the West of the axis, are cut off by rapid dip or sudden depression to the South. It may be conjectured that the line of this depression is prolonged beneath the red rocks of Cheshire to the estuary of the Dee, and it is, perhaps, not improbable that the red marl and sandstone which fills the drainage of the Mersey covers a large extent of depressed coal strata.

Further researches may very probably ascertain the existence of several other buried coal tracts in the midland parts of England near the detached coal fields of Leicestershire, Warwickshire, and Staffordshire.

Forest of Dean.

The Forest of Dean is a singular basin of coal strata with a belt of mountain limestone and *old* red sandstone, rising from a plain of *new* red sandstone, and looking over the vales of Wye and Usk to the similar but more extensive district of South Wales. The general line of elevation in this immense coal field is East and West, and the strata dip from both the North and the South toward the middle; but Mr. Conybeare has shown that along the middle runs an internal axis of elevation, so that the coal field is a double trough.

The elevation of the Mendip Hills, and other tracts of carboniferous limestone in Somersetshire and Gloucestershire, as well as the curious faults in the collieries near Bath and Bristol, must be referred to the same epoch, for the superior strata of red marl and the oolites are unaffected by them.

This short review shows us what extensive changes in the relative level and area of land and water were effected in these regions immediately after the deposition of the coal strata, and similar results have been obtained from researches in various parts of Scotland, Arran, and other Islands, and in the large coal tracts in Ireland.

Ardennes.

In extending our researches to foreign Countries, we must remember that the exact date of the disruption of the strata is determined by limiting the epoch between the date of the formation of the strata broken, and that of the unconformed stratum next incumbent or adjacent. Thus on passing from the Ardennes mountains to Luxembourg, we descend from the elevated slate range to a horizontal mass of new red sandstone, followed by lias and oolites; and in this case it is clear that the elevation of the Ardennes preceded the deposition of *new red sandstone*: but where that stratum is absent, (the general case along the border of these mountains,) we must have been content with inferring that the epoch of the disturbance was older than the *oolites*. On this account it is not easy to fix the date of the disturbances of the coal series of Belgium and the North of France more precisely than by saying, it was anterior to the *oolites*, since these are the oldest strata lying unconformedly over the coal.

The slips and dislocations of the carboniferous system almost invariably agree as to the direction of their slope, compared to the level of the strata with the general law stated before; (ch. i. p. 541.) but there are a few cases of such extraordinary dislocation, as at Valenciennes and in Somersetshire, that the beds of coal and accompanying strata are bent into a sigmoidal flexure, and in part turned completely upside down. Lesser cases of flexure of beds are not unfrequent.

With respect to the degree of distinctness of the planes of the slip, we may remark that this depends very much upon the consolidation of the strata divided. Thus while in limestone and solid sandstone the planes or cheeks of the slip are clearly traced, they are almost obliterated in shales and thin bedded sandstones, either by a bending at the surface of fracture, or by a filling up of the chasm irregularly with fragments from the sides. This applies even to the case of a mineral vein which crosses alternating strata of three different kinds, as in the mines of Aldstone Moor and Swaledale, where the metallic and sparry substances are crystallized in abundance in the open space between the hard cheeks of limestone and gritstone, but are far less plentiful in the obscure and contracted interval between faces of shale. In districts which appear to have been once remarkably subject to igneous eruptions, the fissures of the dislocations are often filled by basalt, both in the subjacent limestone and superior coal tracts, as in the Counties of Durham and Northumberland; but the metallic ores and spars which properly constitute a mineral vein, and which abound so much in the limestone as to give it the name of metalliferous, are very seldom found in the fissures of the coal tract.

Affinity between veins and rocks.

However it is to be explained, there certainly appears to be some affinity between the metallic matter of the vein and the nature of the strata which it traverses; and though no doubt can be entertained that the veins

are posterior to their including rocks, the frequent passage of *strings of ore* into the neighbouring strata, occasional nidiform masses, and solitary crystals of the metallic substances embedded in the interior of the rocks, besides the very remarkable examples of crystals of blende, galena, &c. in the interior of brachiopodous bivalves, seem to prove that the metallic matter has been in these cases deposited by a kind of *secretion.* Nor is this supposition, which is strongly confirmed by observations in the slate districts of Cornwall, in the least inconsistent with what is known of the diffusion of metallic substances by gradual heat much below their melting points. Breislac and Henry mention cases of the transference and collection of metallic matter, (copper) at an ordinary roasting heat, and the well-known example of titanium extricated from the melted iron of our furnaces leads to analogous conclusions. We may, therefore, very consistently maintain, that mineral veins are posterior to the strata which they divide, and yet allow that the transference of metallic substances may have been effected by the ordinary agency of heat, or the influence of electricity, so as to impregnate the strata under particular circumstances with the contents of the neighbouring veins. Such secretions of metallic substances then do not require us to admit the contradictory dogma that the veins occupying fissures are contemporaneous with the strata.

The metallic substances usually yielded by the carboniferous limestone are most of the ores of lead, zinc, and copper, with oxides and carbonate of iron, and the vein—stuff, or matrix, is calcareous spar, fluor spar, sulphate and carbonate of barytes, strontianite, quartz, &c.

Organic Remains of the Carboniferous System.

The mark * signifies that the species to which it is attached has been stated to occur in the slate system also.

PLANTS.

Family.	Name.	British Localities.	Foreign Localities.
Algæ	Equisetum infundibuliforme		Saarbruck.
	dubium	Wigan.	
	Calamites decoratus	Yorkshire	Ditto.
	Suckowii	Newcastle	Ditto, Liege, Anzin, Litry, Richmond in Virginia, Wilkesbarre, Pennsylvania.
	undulatus	Yorkshire	Radnitz in Bohemia.
	ramosus	Ditto.	Mannebach, Wettin, Germany.
	cruciatus		Litry, Saarbruck.
	Cistii		Wilkesbarre, Montrelais, Saarbruck.
	dubius	Ditto.	Zanesville in Ohio.
	cannæformis	Ditto, Newcastle	Langeac, (H. Loire,) Mons, Mannebach, Wettin, and Radnitz, in Germany.
	pachyderma		St. Etienne.
	nodosus	Newcastle	Le Lardin, Department de la Dordogne.
	approximatus		Alais, Liege, St. Etienne, &c.
	Steinhaueri	Yorkshire.	
Filices	C. Mougeotii	Edinburgh.	
	Sphænopteris furcata	Newcastle	Charleroi, Silesia, Saarbruck
	elegans		Waldenburg in Silesia.
	stricta	Ditto, Glasgow.	
	artemisiæfolia	Newcastle	
	delicatula		Saarbruck, Radnitz.
	dissecta		Montrelais, St. George Chatellaison, St. Hippolyte in the Vosges.
	linearis		Swina, in Bohemia.
	Brardii		Le Lardin.
	nervosa.		
	trifoliata	Yorkshire (Artis.)	Anzin near Valenciennes, Mons, Liege, Silesia.
	lendigera.		
	Schlottheimii		Doutweiler near Saarbruck, Waldenburg, and Breitenbach in Silesia.
	fragilis		Breitenbach.
	Hœninghausii	Newcastle	Werden.
	Dubuissonis		Montrelais
	distans		Silesia, Ilmenau.
	gracilis	Ditto.	
	Gravenhorstii		Silesia.
	Loshii	Ditto.	
	latifolia	Ditto.	
	Virletii		St. George Chatellaison.
	affinis, Lind.	Ditto.	
	bifida, Lind.	Edinburgh.	
	caudata, Lind.	Newcastle.	
	crenata, Lind.	Ditto.	
	crithmifolia, Lind.	Ditto.	
	dilatata, Lind.	Ditto.	
	Cyclopteris orbicularis		St. Etienne, Liege.
	auriculata	Yorkshire.	
	flabellata		Berghaupten.
	Several species of Cyclopteris are found at Liege.		
	Neuropteris acuminatus	Newcastle	Klein Schmalkalden.
	Villiersii		Alais. (Department du Gard.)
	Cistii		Wilkesbarre in Pennsylvania.
	rotundifolia	Yorkshire.	Mine du Plessis (Calvados.)
	Loshii	Newcastle	Anzin, Liege, Wilkesbarre.

Family.	Name.	British Localities.	Foreign Localities.
Filices	Neuropteris tenuifolia		Saarbruck, Miereschau, (Bohemia,) Waldenburg, (Silesia,) Montrelais.
	heterophylla	Newcastle	Saarbruck, Valenciennes.
	Grangeri		Zanesville. (Ohio.)
	flexuosa	Bath, Yorkshire, &c.	Saarbruck.
	gigantea	Newcastle	Anzin, Saarbruck, Eschweiler, &c.
	oblongata	Paulton, Somerset.	
	cordata	Leebotwood, near Shrewsbury	Alais, St. Etienne.
	Soretii	Newcastle.	
	Pecopteris longifolia.		
	blechnoides		Werden, near Dusseldorf, St. Priest. (Loire.)
	Candolliana		Alais. (Gard.)
	cyathea		St. Etienne.
	arborescens		St. Etienne, Aubin, (Aveyron,) Anzin, Mannebach.
	platyrachis		St. Etienne.
	Dithiersii		Charleroi.
	polymorpha		St. Etienne, Alais, Litry, (Calvados,) Wilkesbarre.
	oreopteroides		Le Lardin, Mannebach, Wettin.
	Bucklandii	Bath.	
	aquilina		Mannebach and Wettin.
	Schlotthemii		Mannebach, Geislautern.
	pteroides		Mannebach, Aubin.
	Davreuxii		Liege, Valenciennes.
	Mantelli	Newcastle	Liege.
	lonchitica	Ditto	Saarbruck, Silesia, Namur.
	Serlii	Bath	St. Etienne, Wilkesbarre, Geislautern.
	Grandini		Geislautern.
	crenulata		Ditto.
	marginata		Alais.
	gigantea		Abascherhütte, (Treves,) Saarbruck, Wilkesbarre, Liege.
	punctulata		Montagne des Rousses, (Oisans,) Wilkesbarre.
	nervosa		Waldenburg, Rolduc, Liege, Wales.
	obliqua		Valenciennes.
	Brardi		Lardin.
	Defrancii		Saarbruck.
	ovata		St. Etienne.
	Plukenetii		Alais, St. Etienne.
	arguta		St. Etienne, Saarbruck, Rhode Island.
	alata		New South Wales.
	cristata		Saarbruck.
	* aspera		Montrelais.
	Miltoni	Yorkshire	Saarbruck.
	abbreviata		Valenciennes.
	microphylla		Saarbruck.
	æqualis		Fresnes and Vieux Condé, near Valenciennes, Silesia.
	acuta		Saarbruck, Ronchamp. (Haute Saone.)
	unita		Geislautern, St. Etienne.
	debilis		Mines de Ronchamp.
	dentata		Valenciennes, Doutweiler.
	angustissima		Swina, (Bohemia,) Saarbruck.
	gracilis		Geislautern, Valenciennes.
	pennæformis		Fresnes and Vieux Condé, Saarbruck.
	triangularis		Fresnes and Vieux Condé.
	pectinata		Geislautern.
	plumosa	Ditto	Saarbruck, Valenciennes.
	adiantoides, Lind.	Newcastle.	
	heterophylla, Lind.	Ditto.	
	Lonchopteris Dournaisii		Valenciennes.
	cancellata.		
	Odontopteris Brardi		Le Lardin and Terrasson, (Dordogne,) St. Etienne.
	crenulata		Terrasson.
	minor		St. Etienne, Le Lardin.
	obtusa	Near Shrewsbury	Terrasson.
	Schlotthemii		Mannebach, Wettin.
	Caulopteris primæva, Lind.	Somersetshire.	
	Schizopteris anomala		Saarbruck.
Lycopodiaceæ	Lycopodites piniformis		Saxe Gotha, St. Etienne.
	polyphyllus.		
	Gravenhorstii		Silesia.
	Sillimanni.		Hadley on the Connecticut.
	Hœninghausii		Eisleben.
	imbricatus		St. George Chatellaison.
	phlegmarioides	Newcastle	Silesia.
	tenuifolius		St. George Chatellaison.
	filiciformis?		Wettin.
	affinis?		Ditto.
	Selaginites patens	Edinburgh.	
	erectus		Mont Jean, near Angers.
	Lepidodendron selaginoideum	Newcastle	Bohemia, Silesia.
	elegans		Swina, Bohemia.
	Bucklandi	Colebrook Dale.	

Family.	Name.	British Localities.	Foreign Localities.
Lycopodiaceæ	Lepidodendron ophiurus	Newcastle	Charleroi.
	rugosum		Ditto, Valenciennes.
	Underwoodii	Anglesea.	
	taxifolium		Ilmenau.
	insigne		St. Ingbert in Bavaria.
	Sternbergii	Newcastle	Swina in Bohemia.
	longifolium		Ditto.
	mamillare		Wilkesbarre.
	ornatissimum	Edinburgh, Yorkshire	Silesia.
	tetragonum	Newcastle.	
	venosum		Waldenburg, (Silesia.)
	transversum	Glasgow.	
	Volkmannianum		Silesia.
	Rhodianum	Yorkshire	Ditto, Valenciennes.
	cordatum	Durham	
	obovatum		Radnitz, (Bohemia,) Silesia, Fresnes, and Vieux Condé.
	dubium	Newcastle.	
	læve		Comté de la Marche.
	pulchellum		Alais, Liege.
	cælatum	Yorkshire.	
	varians		Wilkesbarre, Saarbruck.
	carinatum		St. George Chatellaison, Montrelais.
	crenatum		Bohemia, Eschweiler, Essen, Zanesville. (Ohio.)
	aculeatum		Essen, Wilkesbarre, Bohemia, Silesia.
	Cistii		Wilkesbarre.
	distans		St. Etienne.
	laricinum		Bohemia, Silesia.
	rimosum		Bohemia.
	undulatum		Ditto.
	confluens		Silesia, Eschweiler.
	Harcourtii, With. / imbricatum	Northumberland. (C. V. Harcourt.)	Eschweiler, Wettin.
	acerosum, Lind.	Newcastle.	
	dilatatum, Lind.	Ditto.	
	gracile	Ditto.	
	Lepidophyllum majus		Geislautern.
	lanceolatum		Montrelais.
	Boblayi		Valenciennes.
	trinerve		Montrelais.
	lineare		Alais.
	intermedium, Lind.	Near Shrewsbury.	
	Lepidostrobus ornatus	Shropshire.	
	undulatus	England.	
	emarginatus	Yorkshire.	
	major	Newcastle.	
	variabilis, Lind.	Ditto.	
	Ulodendron majus, Lind.	Barnsley, near Newcastle.	
	minus, Lind.	Halifax, Craighith, Shields.	
	Cardiocarpon majus		St. Etienne, Langeac. (H. Loire.)
	Pomieri		Langeac.
	cordiforme		Ditto.
	ovatum		Ditto.
	acutum	Newcastle	Ditto.
	Stigmaria reticulata	England.	
	Weltheimiana	Magdeburg.	
	regularis	Germany.	
	intermedia		St. George Chatellaison, Montrelais, Wilkesbarre.
	*ficoides	Leeds, Durham, Northumberland, Derbyshire, &c.	St. George Chatellaison, Montrelais, St. Etienne, Liège, Charleroi, Valenciennes, Muhlheim near Dusseldorf, Silesia, Bavaria.
	tuberculosa		Montrelais, Wilkesbarre.
	rigida		Anzin.
	minima	Anglesea	Charleroi.
Cacteaceæ?	Sigillaria punctata		Bohemia.
	appendiculata	Yorkshire	Ditto.
	peltigera		Alais.
	Cistii		Wilkesbarre.
	lævis		Liege.
	canaliculata		Saarbruck.
	rugosa		Wilkesbarre.
	Cortei		Essen.
	elongata		Charleroi, Liege.
	reniformis	Newcastle	Mons, Essen.
	hippocrepis		Mons.
	Davreuxii		Liege.
	Candollii		Alais.
	oculata	Ditto	Bohemia.
	orbicularis		St. Etienne, Saarbruck.
	* tessellata	Bath, Yorkshire, Newcastle	Alais, Eschweiler, Wilkesbarre.

Family.	Name.	British Localities.	Foreign Localities.
Cacteaceæ	Sigillaria Boblayi		Anzin.
	Knorrii		Saarbruck.
	elliptica		St. Etienne.
	transversalis		Eschweiler near Aix la Chapelle.
	pyriformis		
	Sillimanni		Wilkesbarre.
	subrotunda		Doutweiler, near Saarbruck.
	cuspidata		St. Etienne.
	scutellata.		
	pachyderma	Yorkshire.

	medullaris, Lind.	Ditto.	
	ambiguus, With.	High Heworth.	
	Pitus antiqua, With.	Lennel Braes, near Coldstream.	
	Anabathra pulcherrima, With.	Tweed Mill.	
	Peuce Withami, Lind.	Durham.	
Palmæ	Flabellaria? borassifolia		Swina in Bohemia.
	Nœggerathia foliosa		Bohemia.
	flabellata	Newcastle.	
	Zeugophyllites calamoides		Raña Gunje, near Rajemahl, India.
Cannæ	Cannophyllites Virletii	Yorkshire.	
	Sternbergia angulosa	Ditto.	
	approximata		Langeac, St. Etienne.
	distans	Edinburgh.	
	Poacites lanceolata		Zanesville. (Ohio.)
	æqualis		Terrasson.
	striata		Ditto.
Glumaceæ	Cyperites bicarinata, Lind.	Near Shrewsbury.	
	Trigonocarpon Parkinsonis	England, Scotland.	
	Nœggerathi		Langeac, Coal Mines on the Rhine.
	ovatum		Ditto.
	cylindricum		Ditto.
	dubium		Ditto.
	Musocarpum prismaticum		Ditto.
	difforme		Ditto.
	contractum	Oldham.	
(Class doubtful)	Phyllotheca australis		Hawkesbury River, New Holland.
	Annularia minuta		Terrasson.
	brevifolia		Alais, Geislautern.
	fertilis	Bath	St. Etienne, Wilkesbarre.
	floribunda		Saarbruck.
	longifolia	Camerton	Geislautern, Silesia, Alais, Wilkesbarre.
	——— B.		Charleroi, Terrasson.
	spinulosa		Saxony.
	radiata		Saarbruck.
	Asterophyllites equisetiformis		Mannebach, (Saxony,) Rhode Island.
	rigida		Alais, Valenciennes, Charleroi, Bohemia
	hippuroides		Alais.
	longifolia	Newcastle	Eschweiler.
	tenuifolia	Ditto.	Silesia.
	tuberculata	Ditto.	Germany.
	delicatula		Charleroi, Anzin.

Family.	Name.	British Localities.	Foreign Localities.
(Class doubtful.)	Asterophyllites Brardi		Terrasson.
	dubia	Newcastle.	
	diffusa		Radnitz, Bohemia.
	grandis, Lind.	Ditto.	
	foliosa, Lind.	Ditto.	
	galioides, Lind.	Barnsley.	
	Volkmannia polystacha		Waldenburg. (Silesia.)
	distachya		Swina. (Bohemia.)
	erosa		Terrasson.
	Polyporites Bowmanni, Lind.	Near Wrexham.	

Nearly all the names of fossil plants are taken from Brongniart; the few from Lindley and Hutton, from Sternberg and Witham, are marked by suitable abbreviations.

Analogy to existing plants.

The following observations by M. Adolphe Brongniart contain nearly all that can be at present advanced concerning the physical conditions which governed the growth of these plants. We shall first remark that since the date of M. Brongniart's Essay, true coniferæ have been discovered in the English coal districts, and that his reference of sigillaria to the tribe of arborescent ferns appears open to very serious objections, and is perhaps not generally allowed. Besides the few coniferæ and monocotyledones, "the flora of this epoch is composed almost wholly of vascular cryptogamous plants, so that out of 260 species 220 belong to this class. But, though evidently ranging themselves in the families of equisetaceæ, filices, and lycopodiaceæ, these plants differ from the species, and often from the genera now in existence, in several points of their organization, and especially by their gigantic size. At this period there existed equiseta more than ten feet in height, and five or six inches in diameter, tree ferns forty or fifty feet, and arborescent lycopodiaceæ sixty or seventy feet high. The essential characters of this 'primary' vegetation are the *numerical predominance* and *great magnitude* of these cryptogamic plants.

"It has been long observed, that the plants of this age resembled generally those of the hot, rather than of the temperate regions of the Globe; but since the fossil plants have become much better known, and their analogy with existing tribes founded upon a more thorough examination, their relation to the plants of Equatorial regions may be established on a more solid basis. All cryptogamic plants acquire greater size, in proportion as the climate is hotter; or rather, in cold climates none but very small species of this class are found, while in tropical regions we have, in addition, many of large size. The ferns of cold and temperate climates are upon the soil, or their stem rises only a few inches in height; those of tropical regions grow to ten or twenty feet: the smallest equiseta known are those of Lapland and Canada; the largest grow in the West Indies, and Equinoxial America; the lycopodia of our climates are never above five or six inches high, those of tropical regions are three or four times as high.

"The *numerical predominance* of the cryptogamic tribes in the carboniferous epoch is such that, while in the existing order of Nature they are to the whole number of plants known as 1 to 30, they were in that ancient epoch in the proportion of 27 to 30."

If we seek to determine by comparison with *particular or local existing floras*, the probable circumstances under which cryptogamic plants grew to such preponderance in the carboniferous epoch, we shall be guided by the observations of Brown and D'Urville to some important results. According to these eminent Botanists, the family of ferns is subject to the influence of two causes, which determine their mode of distribution over the Globe; heat of climate, and the influence of the humid air and uniform temperature of the sea. Hence, when the circumstances depending on proximity to the sea are equal, these plants are more abundant in the Equatorial than in colder regions, but in the same zone of climate they are much more abundant in isles than on continents. In the temperate parts of the Continent of Europe, under favourable circumstances, they are to the phanerogamic tribes as 1 to 40; within the tropics Brown states the ratio as 1 to 20, and in unfavourable situations as 1 to 26. Under the same latitude, this proportion becomes much greater in Islands; in the West Indies the ferns are as 1 to 10, instead of 1 to 20, as in favourable situations on the Continent of equinoxial America; in the South Sea Islands 1 to 4, or 1 to 3; while on the Continent of India and in the tropical part of New Holland the ratio is 1 to 26. At St. Helena and Tristan d'Acuyna the cryptogamia are to the phanerogamia as 2 to 3, and in Ascension nearly as 1 to 1.

From these examples it is plain, that the smaller the isles, and the more remote they are from great continents, the larger is the proportion of ferns growing there; and we may conceive that if such islands were alone in the midst of a vast ocean, or formed only scattered points or little clusters without any great continent, their proportion of ferns would be still greater, and the cryptogamia become the predominant group. Geologists have, from independent considerations, inferred that at the time of the formation of coal, the extent of land in the position of our present continents was very small compared to the wide surface of the sea; and thus Geology and Botany appear to agree in determining that at this period, and in the situations where afterwards coal was formed, land existed only in small islands, amidst extensive seas. On these islands, under perhaps a more than tropical climate, in an atmosphere charged with moisture, we may believe that those gigantic cryptogamia grew which have produced so large a proportion of the extended coal beds of the older carboniferous epoch.

POLYPARIA.

Family.	Name.	British Localities.	Foreign Localities.
Cellulifera	Flustra crinoidea, Miller.	Arran.	
	Retepora flustraformis, Mart.	Middleton, Derbyshire, Arran.	
	elongata, F.	Rutherglen, Lanark.	
	Cellepora Urii, F.	Rutherglen.	
	Aulopora compressa, G.		Ratingen.
	Catenipora	Winster.	

Family.	Name.	British Localities.	Foreign Localities.
Cellulifera	Tubipora ramulosa	Mendip, Westmoreland, Ireland.	Olne, Limburg.
	Syringopora reticulata		Olne.
	radiata, Mart.	Winster.	
	strues, L.	Westmoreland.	
	tubularia L.		Liege.
	Favosites septosus, F.	Scotland.	
	depressus, F.	Ditto.	
	ramosus	Arran.	
	*Calamopora polymorpha, G.		Namur, Elberfeld.
	Millepora, undescribed, Sp.	Near Kirby Lonsdale, in thin beds.	
	undescribed, Sp.	Near Middleham, near Kirby Lonsdale.	
Lamellifera	Cyathophyllum excentricum, G.		Ratingen.
	pentagonum, G.		Namur.
	Lithostrotron striatum, Park	Wales.	
	floriforme, Mart.	Bristol.	
	marginatum, F.	Scotland.	
	Caryophyllia fasciculata	Bristol	At Namur two species of Caryophyllia.
	duplicata, Mart.	Bakewell	
	affinis, Mart.	Winster	
	juncea, F.	Rutherglen	
	Turbinolia fungites, F.	Yorkshire, Rutherglen, Ireland	Liege, Namur.
	Astrea undulata, Park	Bristol.	
	Porites cellulosa, Park	Mendip.	
	*Amplexus coralloides, Sow.	Anglesea, Limerick.	

These thirty or more species of polyparia appear almost wholly distinct from those of the slate system, yet they belong mostly to the same genera. They have as yet been little noticed in the carboniferous limestone of Belgium and Westphalia. No polyparia have yet been seen in the proper coal measures; they all belong to the subjacent limestone group.

Radiaria.

Family.	Name.	British Localities.	Foreign Localities.
Crinoidea	Pentremites ellipticus, Sow.	Preston.	
	Derbiensis, Sow.	Derbyshire, Ireland.	
	globosus	Bath.

	Cyathocrinus planus	Northumberland.	
	quinquangularis	Bristol.	
	*rugosus	Whitwell, Yorkshire.	
	Actinocrinus *30 dactylus	Ditto, ditto, Ireland.	
	polydactylus	Whitwell, Mendip.	
	lævis		Ditto.
	Gilbertsoni	Whitwell, Yorkshire.	
	granulatus, G.		Ditto.
	Rhodocrinus *verus	Whitwell, Bristol, Dean Forest.	
	quinquangularis	Whitwell.	
	Eugeniocrinus, undescribed	County Fermanagh, Ireland.	
Echinida	Cidaris, with large mammellæ and muricated spines. Phil. MS.	Yorkshire, Northumberland, Westmoreland.	

No radiaria have yet been seen in the proper coal measures, they all belong to the subjacent limestone group, which in some extensive tracts is almost wholly composed of their disjointed columns and other parts. The names are principally from Miller's Work on the crinoidea; where other authors are quoted, their names are appended to the particular species described by them.

Conchifera.

The names in the preceding catalogue of conchifera are almost wholly taken from Sowerby's *Mineral Conchology*; where other authors are quoted, their names are appended to the particular species described by them.

The conchifera of the carboniferous system admitted in the preceding lists amount to 112.

Plagymyona 25, mesomyona 17, brachiopoda 70. Of these 3 plagymyonous, 7 mesomyonous, and 31 brachiopodous, are said to be also found in the slate system. On this subject the remarks which follow the enumeration of the conchifera of the slate system may be referred to. Mesomyonous bivalves have now become more numerous, and the enormous preponderance of brachiopoda over the other orders of bivalves is reduced from 6 to 1 to about 2 to 1.

Of these 112 species, 5 are generally allowed to be fluviatile or lacustrine; and their number, if augmented by the yet undescribed species in England, may very probably amount to 10. Nearly all the marine tribes occur in the limestone group below the coal measures; all the fresh-water species lie in the coal measures; but there is one thin layer of marine shells extensively spread in Yorkshire, in the midst of the coal measures, *above certain fresh-water layers* and *below several others*. No fresh-water shell lies in this bed. Hence the series of operations by which that coal field has been formed evidently includes one period of marine, and two of fluviatile or lacustrine action, subsequent to the general and long-continued action of the sea, which deposited the mountain or carboniferous limestone. There is no disturbance of strata nor any thing to indicate local movement during the deposition of the coal, and it is presumed that the alternation of marine and fresh-water deposits, here certainly proved, was occasioned by causes acting at a distance. An additional memoir has been promised on this subject. (See p. 590.)

Mollusca.

	Name.	British Localities.	Foreign Localities.

	several new species	Yorkshire and Lancashire.	
	carbonarius, G.		Ditto, Werden, Wettin.
	Henslowi	Isle of Man, Yorkshire.	

The mollusca of the carboniferous epoch are but imperfectly known, notwithstanding the labours of Sowerby, Fleming, and others, and we can hardly venture to expect that the numerical relations of even the leading divisions will remain unchanged, when the numerous additional species shall have been described. The present ratios are, gasteropoda about 55, cephalopoda 57, of which 16 are monothalamic, which are not very different from the proportions in the slate system. Above this epoch, monothalamic cephalopoda disappear wholly until new tribes of them are recognised above the chalk. It is proper to mention that the situation which we assign to bellerophon among the cephalopoda is not admitted by all Naturalists. The names of the mollusca are from Sowerby, except where other authors are quoted.

Saliferous System.

It has been shown that the consolidated deposit of coal was subject to the effects of a very general eruption of igneous agency from beneath, and that in this manner the whole arrangement of those deposits was altered, and many parts of the bed of the sea uplifted to form dry land. In the large but very irregular area left between these islands of carboniferous strata, the sea began to deposit limestones commonly charged with magnesia, sandstones remarkably coloured with red oxide of iron, and clays and marls of red, blue, and white colours; the whole series being, in general, far from rich in organic remains, seldom traversed by metallic veins, and not so much dislocated by faults as the older strata. Salt, in beds or nodules, accompanied by gypsum, lies very commonly in this series of rocks, and hence it may be termed emphatically the saliferous system. Generally, its stratification is wholly unconformed to that of the subjacent coal measures, on whose elevated edges, breaks, and dykes, its planes rest level and undisturbed.

In the composition of this group we find traces of all the various operations of the sea; limestones crystallized, compact, brecciated, conglomerated, and earthy, full of magnesia, or containing carbonate of lime with little or no admixture. Locally rich in organic remains, but generally devoid of them; sandstones coloured red, blue, or white, in stripes and spots, fine grained, coarse grained, or full of innumerable pebbles, derived from primary and secondary rocks; clays and marls of many various hues; both the sandstones and clays locally productive of the remains of saurians, shells, and plants, but over large tracts wholly destitute of them. These

Geology. Ch. II.

organic remains are partly analogous to those of the carboniferous system, and partly to those which occur in the more recent oolites, and the whole formation, though so peculiar in character as to be readily, and indeed unavoidably, separated from both those systems, offers by many resemblances, besides its intermediate position, a natural transition from the one to the other.

This may perhaps appear to those who only have seen the saliferous system in England, where its total unconformity to the coal, and dissimilitude to the strata above and below, are matter of notoriety, a proposition deserving further explanation. The facts on which it rests will be found in the following pages, and they will give reason to presume that when we have assembled data sufficient for satisfactory induction, those *interruptions in the series* which appear to indicate great and sudden revolutions will be proved to be merely local, and to arise from the *omission* in certain situations of strata elsewhere deposited in great force.

It has already been stated that in the Island of Arran the primary strata are succeeded by a very thick series of red and white sandstones and conglomerates, and that coal measures and carboniferous limestone lie included in this mass like subordinate or local formations. The conglomerates below the limestone represent the old red sandstone, and the upper sandstones above the coal represent the new red sandstone formation, and it might be possible to include the whole of the carboniferous and saliferous systems of rocks together under the name of red sandstone formation. This is the view of the subject taken by Von Hoffman, from observations in the North-Western part of Germany, where in a mass three or four thousand feet thick of red and white sandstones, lie the diminished strata of coal.

Nevertheless, these cases, though affording very instructive inferences as to the continuity of the operations of Nature, are not to be taken as general types of the series of strata, and throughout the greater part of the British Islands, as well as in the South-East of France and in Germany, the saliferous red sandstone series, with its accompanying limestones and marls, is a distinct system of strata, characterised by peculiar features of mineral composition, and organic contents, and marked by a general aspect of physical geography.

England.

In England, supposing all the parts of the saliferous system of rocks present in one section, we should have, reposing unconformably on the coal strata, the following classification, beginning from above.

4. Series of coloured marls	Purple coloured marls below the lias.
	Alternations of red and bluish white marls, with layers and nodules of gypsum.
	Thin layers of argillo-calcareous stone.
	Red and bluish marls with gypsum and beds of rock salt.
3. Variegated red and white sandstone (Pœcilite of Conybeare)	Red and white sandstone, mostly fine grained, and often impregnated with salt.
	Red conglomerate, full of pebbles of older rocks.
2. Magnesian limestone.	Red and white marls.
	Thin bedded compact limestone, with very little magnesia and few organic remains.
	Red and white marls and gypsum.
	White, yellow, or reddish magnesian limestone in thick beds, crystallized, compact, or earthy, often full of sparry cavities, and containing marine organic remains.
	Marl slate, in thin layers, occasionally enclosing fishes.
1. Yellow or purple sand and sandstone and marl	An extremely variable series of sandstones, sands, and clays, of various colours, irregular thickness, and much local diversity of character.

Range of the Saliferous System in England.

Of the beds included in this arrangement, the calcareous strata are perhaps the least extensive, yet, as usually happens, they are most regular and continuous in their ranges, and most consistent in characters, and afford the best data for the classification of the others. By looking at Mr. Smith's, or Mr. Greenough's Geological Map of England, the extent of the range of magnesian limestone may be observed from the North side of the Tyne uninterruptedly to the Tees, between which river and a place called Thornton Watlas, it is known only in a few points, though probably it exists continuously beneath the superficial accumulations of gravel. From this point to Bilborough, near Nottingham, its course is uninterrupted.

Below it, in a narrow, irregularly parallel tract to the West, reposing on all the members of the coal formation indiscriminately, runs the lower series of sandstones and marls, above on the East through Yorkshire and Nottinghamshire ranges the conglomerate red sandstone, and upon this lies, through Durham, Yorkshire, and Nottinghamshire, the series of upper coloured marls and gypsum.

Cumbrian district.

On the Western side of the summit ridge of the North of England, the vale of the Eden is filled by the new red sandstone formation, consisting principally of coarse or fine-grained red sandstone, and red marl above, with, in one place, a remarkable series of conglomerate, or rather brecciated beds at the bottom, and in another a distinct deposit of magnesian limestone. The former are seen at Kirby Stephen in the angle between two lines of dislocation and afford a very instructive point of comparison with an analogous deposit in Somersetshire, known by the name of millstone. It has a basis of red sandstone almost entirely filled with angular fragments of different sizes of the neighbouring limestone strata; it is disposed in vast unequal beds, with large distant joints almost invariably ranging North and South, lies with a dip to the East between the lines of two dislocations of the carboniferous limestones, to the violence accompanying which its own production was probably owing. It is not in general magnesian, yet some yellow beds probably contain that substance, and thus we are led to refer its production to the date of the lower parts of the magnesian limestone.

No further trace of beds analogous to the magnesian series of Yorkshire and Durham occurs, in the Westward extension of the new red sandstone group round the Cumbrian mountains, till we reach Whitehaven, where magnesian limestone and conglomerate, lying in red sandstone, are sunk through in the coal pits, and seen in the high cliffs against the sea towards St. Bee's Head. From Professor Sedgwick's examination of this district we learn that the section here presented is more closely similar to that of Yorkshire than was previously supposed, and that the following groups are uniformly laid upon the coal system.

3.	Variegated red sandstone of St. Bee's Head.
2. Magnesian limestone.	Red marl and gypsum.
	Magnesian limestone sometimes replaced by or alternating with magnesian conglomerate.
	Magnesian conglomerates, analogous to those in the vale of Eden, and various parts of Yorkshire.

Geology. Ch. II.

1. { Coarse reddish sandstone of great thickness on the whole unconformed to the coal measures, but also in part unconformed to the rocks above, which lie in its hollows.

In their Northward extension beyond the Solway Frith to Dumfries-shire and Galway, the red sandstone strata do not exhibit any traces of magnesian limestone.

Midland Counties.

Beyond the Southern termination of that rock, near Nottingham, the variegated red sandstones and coloured marls spread themselves over the whole area between Leicester, Warwick, and Worcester, on the one side, and Shrewsbury, Chester, Liverpool, on the other, and extend Northwards to Manchester, Leek, and Ashbourn. Yet in all this immense area, except at Ardwick, near Manchester, and near Shrewsbury, we nowhere find any deposits analogous to the magnesian limestone. At Ardwick a limestone is dug containing, as we have been informed by Dr. Henry, magnesia; and we may believe that its geological situation is similar. In this neighbourhood also, as at Worsley collieries, we appear to recognise the lower red sandstone of Yorkshire, in several places overlying the coal beds, and it is probable that further examination may extend these points of agreement. Near Shrewsbury, likewise, the coal strata are preceded by what appears to correspond to the lower red sandstone, and upon this lies a porphyritic magnesian conglomerate.

South of England.

South of Worcester the variegated sandstones and marls, the latter predominating, pass down the Vale of the Severn, fill up the winding intervals of the dislocated carboniferous limestone, partly cover the coal basins of Somersetshire, spread in the vales of the Parret and the Exe, and reach the sea at Exmouth.

The only parts of this extensive range where magnesian rocks appear distinctly, is amongst the limestone and coal tracts of Somersetshire and South Gloucestershire. Along the sides of Mendip magnesian conglomerates of considerable extent separate the limestone from the red sandstone, and produce the ores of zinc; a similar deposit, in similar relation to the older limestone, appears along the Avon below Clifton, and at Radstock and other places it is pierced in the collieries, at or near the bottom of the red sandstone, and receives the name of millstone. Conglomerates of a very singular, even porphyritic, character occur near Exeter, in the lower part of the variegated sandstone and marls, and from a general review of the whole subject, Professor Sedgwick classes the conglomerates of Exeter, Somersetshire, and Shropshire, with the lower or conglomerate portion of the magnesian limestone of the North of England. Some doubt may perhaps yet remain as to the propriety of including in this system the red conglomerate of Exeter, which is by Mr. De la Beche ranked with the rothetodteliegende, but in the other points the inference appears certain.

From this view of the subject which we fully adopt, it would appear that the difference of the saliferous system, in different parts of England, arises rather from the limited continuity of the beds, than from any great variation in their quality or relations. The series of the saliferous system is perhaps nowhere more complete than in the interval between the Wharfe and the Dun, yet even here several beds are deficient. The marl slate and conglomerate limestones are better studied in Durham, the upper coloured marls are better exhibited in Nottinghamshire, and the beds of salt must be examined in Cheshire.

Remarks on certain Members of the Saliferous System in England.

Geology. Ch. II.

Variegated sandstones and clays.

The variegated sandstones and coloured clays of the British series, being destitute of organic remains, and subject to no very remarkable changes of character, what has been said will suffice for the purpose of comparison between them and the analogous deposits in other parts of Europe. But before we proceed to this comparison, it will be useful to describe more particularly the general characters of the terrace of magnesian limestone, and its associated strata, which occupies so remarkable a range in the North of England. The table already given will explain the relation of the several members of this group, and we shall at present confine our attention to the calcareous portions. The most ample details on every point will be found in Professor Sedgwick's Paper in the *Geological Transactions*.

Marl slates.

Immediately above the lower red sandstone in the excavation for the Stockton Rail-road, were found in ascending order, (1.) thirty feet of light-coloured, silicious sandstone in thin beds, alternating at the top with blue calcareous slate. (2.) Nine feet of yellow calcareous shale and marl slate, some of the beds incoherent and sandy. In this marl slate about two feet above the sandstone were found many impressions of vegetables (ferns) and fishes of the genus palæothrissum. The higher and more compact beds also contained productæ, spiriferæ, and terebratulæ. The shales or marls of this series are sometimes highly bituminous. (3.) Twenty feet of thin calcareous beds with marly partings.

These slaty marls and limestones have a very irregular extent even in Durham, and are imperfectly traceable in Yorkshire. They are perhaps best exhibited at Garforth Cliff, on the road from Leeds to Selby, where they are full of axinus obscurus, and contain a species of producta not yet described. Deposits somewhat analogous are described by Professor Sedgwick near Bolsover. Little or no magnesia is found in this part of the series.

Yellow magnesian limesto[ne]

The yellow magnesian limestone whose extreme thickness between the Aire and the Dun certainly exceeds 300 feet, exhibits the most astonishing diversity of mechanical structure, without a corresponding diversity of chemical composition or definite geological divisions. Several varieties yield upon analysis carbonate of magnesia and carbonate of lime, in the simple proportion of atom to atom, (for example, the building stone of Huddleston and Warmsworth,) and in almost all the proportion of magnesia is large. In the Southern part of its range, the structure of the rock is generally crystalline, and the crystals (rhomboids) being small, and often tinged of a reddish or yellow colour, the whole might be easily mistaken for sandstone. On the contrary, in the Northern part of its range, a concretionary structure is often observed, and thus globular masses of carbonate of lime of various magnitude compose beds of stone or lie loose amongst a quantity of yellow, powdery, calcareo-magnesian carbonate. But the variety of the appearances presented by this kind of structure is so great, that on entering a quarry near Sunderland we are struck by the organic aspect of the whole escarpment, as if it had been a reef of coral. On the coast of Durham beds of this structure appear associated with masses of brecciated limestone, but very irregularly, and under circumstances not easily explained, without sup-

posing the deposits to have been subject to repeated local and violent disturbance.

Certain beds of this rock in Yorkshire and Derbyshire are very compact; in Durham some are composed of numerous thin, incoherent layers. In several places North of the Dun and near Tadcaster oolitic portions are distinguishable.

But by far the most plentiful of all the varieties of this changeable rock, especially to the North of the river Wharfe, is a loose earthy mass of indistinct beds, with hollow geodes of crystallized carbonate of lime, and numerous veins or strings of the same substance, dividing the rock into angular cells, and helping to hold it together. This character of crystallized cavities and spurry strings is very common to the whole formation, and we occasionally find oxydulated iron, sulphate of strontian, or sulphate of barytes in these cavities. In the quarries at Weldon occur layers of silicious nodules, analogous to the chert lumps in limestone, in oolite, and green sand, and to the flints in chalk. Veins of sulphate of barytes cross the magnesian limestone in several places near Ferrybridge, and near Wetherby. Galena occurs in it at Mansfield and at Warmsworth near Doncaster in small veins, and in other places in detached crystals, as does also sulphuret of zinc; carbonate of copper lines some joints of the rock at Newton Kyme near Tadcaster, at Warmsworth, and at Farnham near Knaresborough; muriate of soda has been obtained by Mr. Holmes from the red beds of Mansfield, and a solitary lump of red rock salt was found in connection with it near Pontefract.

Organic remains of retеporæ, crinoidea, brachiopodous bivalves, and other shells of mollusca, occur in this rock, in by far the greatest abundance near Sunderland in Durham; they are much less plentiful in the upper parts of the rock in Yorkshire between the Dun and the Wharfe; and only a few species obscurely show themselves in Derbyshire and Nottinghamshire. There is a great analogy between the organic remains in the magnesian limestone of Durham, and those of the older carboniferous limestone, and it especially deserves attention that in this rock the genus producta is seen for the last time as we ascend the series of strata, while no ammonite has yet been found in it.

Above the yellow magnesian limestone is a series of gypseous red and white marls, fifty feet thick or more, and this is surmounted by the upper laminated limestone.

Upper laminated limestone.

This rock is not coextensive with the yellow limestone, but has a more limited range, scarcely extending beyond the boundaries of Yorkshire. It is most fully developed in the tract between Tadcaster and Tickhill, and may be examined advantageously at Brotherton and Knottingley, where enormous quantities of it are burned annually to lime for agricultural purposes.

It here reaches to about fifteen yards in thickness, and is composed of a vast number of small irregular layers, separated more or less by partings of marl, and obscurely united into uneven and often undulated beds. The stone is nearly devoid of magnesia, its substance is usually compact, so as even to fit it imperfectly for the purpose of lithography; it is remarkably full of dry cracks, which have dendritical faces, and small cavities lined with crystallized carbonate of lime appear in the thicker layers. The thickness of the layers increases suddenly, or the beds become more consolidated toward the bottom, and in this part the crystallized cavities become more numerous and larger, the stone is less compact, holds more magnesia, and is of no value for lime. The prevalent colour of the stone is a smoke-grey, which is often disposed in spots or stripes, and the separating marls are generally light grey, but often purplish, and further South reddish.

Organic remains occur but very rarely, and in the lower beds only. They are very imperfect in general, but appear to be of the same species as others from the yellow limestones of the same vicinity.

Further North, at Nosterfield, these beds change their aspect considerably, so as to resemble closely some kinds of carboniferous limestone, a resemblance increased by the presence of productæ, and the occurrence of galena. About Doncaster this rock assumes a redder aspect, and contains some beds full of magnesia. It is then said to be a *hot lime*, and like the product of the yellow limestone, is injurious if laid on the land in large quantity.

The stony beds mentioned in the general classification of the saliferons system occur at a few points about Gainsborough in Lincolnshire, and Tuxford in Nottinghamshire, as we learn from Mr. Smith, who distinguishes it by the provincial title of *waterstone;* and perhaps the hard white beds at Newnham in Gloucestershire may be referred to the same rock. Its course remains to be further traced, and deserves attention as perhaps affording a term of comparison with the magnesian layers described by M. Elie de Beaumont in the variegated marls of Alsace.

Rock salt.

The following abstract of Mr. Holland's Paper in the *Geological Transactions*, vol. i., will convey a good notion of the situation and mode of deposition of the rock salt in Cheshire.

Character of the country.

Cheshire unites with the Southern part of Lancashire and the Northern part of Shropshire into a great plain, fifty miles long from North to South, and about twenty-five or thirty wide. It is bounded on the East and on the West, and interruptedly on the South, by carboniferous ranges of hills; and the internal area is divided by two ranges of rising ground into three minor plains, which serve to conduct the Dee, the Weaver, and the Mersey to the Irish Channel. The range of Delamere Forest on the West, and an undulated tract ranging nearly Westward to Halton and Runcorn, define the drainage of the Weaver, and include the most abundant sources of salt. Scarcely any rock salt is found except in this limited tract. On approaching the estuary of the Mersey, the ridges which bound the plain approach one another at two points, and suggest the idea of the included plain having been once a lake.

The salt which lies under this plain is found to thicken, at least partially, toward the contraction of the valley; it does not, however, lie beneath the whole surface of the low ground, nor indeed in one connected mass, but occurs in detached masses of limited area. The rock salt of Northwich ranges North-East and South-West, and its breadth is about three-quarters of a mile. The upper bed is thickest on the North-West, and thins off toward the South-East.

Two beds of salt at Northwich, &c.	Three beds at Lawton.
Rock salt.. 20 to 30 yards.	42 yards marl, &c.
Parting of marls, &c. } 11 yards.	4 feet salt.
Rock salt 35 yards known.	10 yards marl, &c.
	12 feet salt.
	15 yards marl, &c.
	24 yards salt.

The upper bed has been worked through only at North-

wich and Lawton. No marine exuviæ occur over the salt, or in any way associated with it. The purest part of the salt in the upper bed is about three or four yards above the bottom of the bed, and about four feet in thickness; the purest part of the lower bed is twenty or twenty-five yards deep in it, and five or six yards thick, below which the salt becomes earthy as above. This is the part worked. The salt is not stratified, but divided into vertical prisms of various polyhedral forms, and different magnitudes, sometimes a yard or more in diameter. The sides of these prisms consist of pure white salt. Gypsum abounds in the marls associated with the salt, the most abundant variety being the fibrous kind.

Mr. Holland supposes that what is now the salt field was once a salt-water lake, separated from the sea by a natural dam; that the evaporation of the water caused the precipitation of the salt, and that it was afterwards covered with the laminated marls. To account for so much salt, he imagines that the sea might often overpass the dam.

Perhaps we may say that there was here a lake of salt water, of which the deposit went on gradually, and that at intervals violent floods filling it with muddy matter, this was precipitated with gypsum, but without salt, but that afterwards the water again subsiding, salt fell as before. If the floods came in from the sea, this might explain the correspondence in character of these gypseous marls, and those which elsewhere belong to the Keuper era.

Section. Northwich.

22	36	0	0	Rock Salt sunk into 35 or 36 yards.

English Geologists have, till lately, commonly believed that rock salt was the peculiar production of the red marl and red sandstone; but the mines of Wielitzka are in green sand, those in the Salzburg Alps in limestone of the oolitic period.

By far the larger proportion of ordinary springs, from whatever strata they issue, yield muriate of soda, sometimes in very large quantity, and it is important to know that bromine and iodine, which are stated to be always existent in the actual sea water, very generally accompany the muriatic salts in common springs. This is most remarkably the case with bromine. (See *Phil. Trans.* 1830.) The rock salt of Cheshire is perhaps entirely devoid of bromine and iodine, though the brine springs of the same district are found to contain both. The reason of this may be that the hydrobromic and hydriodic salts have not the same ratio of solubility as the muriate of soda.

Saliferous System of Europe.

General view.

We are now at liberty to consider the characters of the saliferous system as they appear in the other parts of Europe, which have been accurately examined by Geologists. This comparison is much facilitated by the mutual understanding now so general between English and foreign observers, and the subject is made familiar to our countrymen by the published inferences of Sedgwick, Voltz, and De Beaumont. The Rhine in its Northward course from Basle divides into two unequal parts an immense area, in which the saliferous system mantles round the primary ranges of the Vosges, Schwartzwald, Odenwald, Spessart, Thuringerwald, and Harz mountains. The natural boundaries of this irregular area, are, on the West, South, and South-East, the French, Swiss, Swabian, and Bavarian ranges of Jura limestone; on the North-West, the slate formation of the Ardennes, Nassau, and Westphalia; on the North the tertiary plains of Northern Germany. Over all this immense tract, the saliferous system contains a calcareous stratum at present unknown in Britain, called the Muschelkalk, a rock which, in some of its external characters, particularly its smoke-grey colour, and association with marls, bears a considerable analogy to the upper layers of the magnesian limestone formation of England, but by the occasional abundance and general character of its organic remains is strongly assimilated to our lias.

Organic remains.

In several districts different portions of the sandstones and marls contain organic remains both animal and vegetable, which are entirely distinct from those yet known to belong to the older formations, but greatly resembling those of the lias and oolites, so that the foreign localities of the new red sandstone series supply us with those links in the chain of general Geological facts which are wanting in Britain, and for want of which English Geologists have been accustomed to view in too absolute a light the distinction between the carboniferous and the oolitic formations. On the other hand, in the greater part of the saliferous system on either side of the Rhine, beds corresponding to the magnesian limestone of England are entirely unknown. It is chiefly along the line of the South-Western face of the Thuringerwald, prolonged to the North-West as far as Münden, in the drainage of the Weser, along the Southern and Eastern borders of the Harz, and on the North-West side of the slate formation connected with the Erzgebirge, in the drainage of the Elster, that the zechstein and rauchwacke represent on a greater scale the yellow magnesian and upper laminated limestone of the North of England.

Salt which, as above explained, occurs in England in beds only in the variegated marls, is found in one or other side of the Rhine in every bed of the system.

From these remarks it is evident that there is a great general resemblance between the characters of the saliferous formation as it exists in Germany, France, and England; but to make the differences equally apparent, it will only be necessary to fix our attention upon two districts in particular, *viz.*, the Vosges mountains, which range to the North-East parallel to the Rhine, and the district in the North-East of Upper Germany, adjoining the Thuringerwald and the Harz mountains.

The general succession of strata in the saliferous system round the Vosges mountains may be well seen on the road from Metz to Strasburgh; and the minuter details of the beds have been ascertained by those eminent Geologists, Voltz and Elie de Beaumont; to the former of whom we owe the discovery of most of the vegetable fossils of these rocks, and to the latter a valuable discussion of the relations of the formations.

Between the bottom of the oolitic system and the top of the saliferous system occurs, about Luxemburg especially, a peculiar sandstone, which has hardly been distinctly recognised in any other situation. Below this, in descending order, is the following series of strata.

Section of the Vosges.

4. Variegated marls, Keuper of Germany, marnes irisées of France.—Red, pale blue, greenish, &c., with gypsum occasionally interstratified, especially near the top, with beds of sandstone of different kinds, containing plants of the families calamites, equisetaceæ, lycopodiaceæ, coniferæ, cycadeæ, &c., univalve and bivalve shells, remains of saurians and chelonida.

In these coloured marls, above the middle, lies a regular bed (six to ten feet thick) of extremely compact magnesian, yellow limestone, without fossils, and under it, in several places, black schistose marls; in this part, also, gypsum is especially abundant. In several situations, thin bands of reddish limestone occur, alternating with anhydrite.

3. Muschelkalk.—Limestone, generally compact, of a light grey or smoky colour, with partings of marl, containing peculiar encrinites, with ammonites, plagiostomata, and other shells analogous to those of the oolitic system, and remains of reptiles. Near Luxemburg it is very thin, and may easily be mistaken for lias; near Saverne it is much thicker, and more characteristic. At Bourbonne les Bains it is a true magnesian limestone. As before observed, it does not exist in England.

2. Variegated red sandstone. (*Bunter sandstein* of Germany, *grès bigarré* of France)—Extremely similar to the new red sandstone of England. This also contains, locally, abundance of organic remains, both animal and vegetable.

1. The strata above named rest, in some places unconformably, upon a vast thickness of red sandstone, in general much coarser, and more like a conglomerate than the variegated red sandstone; the pebbles of quartz, which it contains in abundance, appearing to be derived from the ruins of portions of the primary rocks of the range of the Vosges. The magnificent precipices down which the road descends to Saverne, among grand old woods and torrents, are formed by this rock, and the resemblance which it bears to the old red sandstone conglomerate of Monmouthshire, is such as to bias the English Geologist strongly in favour of that approximation. In other cases, and especially in hand specimens, this rock appears to resemble the coarse red sandstone of Dumfries-shire and of Penrith Beacon, and as these rocks certainly overlie the carboniferous series, this comparison may, perhaps, be exact. The Northern part of the Vosges mountains being wholly composed of these grit rocks, and coal beds being found at many points in the same vicinity, the incumbency of the red sandstone upon the coal is satisfactorily proved.

The lower part of this thick arenaceous group, which rests upon the coal series, is usually of a friable and fragmentary nature, containing admixtures of porphyritic masses, which strongly assimilate it to the red sandstone conglomerate of Exeter, and the red sandstone, expressively so called, of the North of Germany. The upper part, also, gradually becomes finer grained, and more like the ordinary variegated red sandstone; but as in several places this latter rock rests unconformably upon the other, we are justified in adopting the opinion of Voltz and De Beaumont, that it is a portion of the red sandstone series, almost peculiar to the Vosges mountains, and may, therefore, be characterised as the *grès des Vosges*.

North-East of Germany.

The North-East of Germany gives us the following section of the saliferous system.

5. Variegated marls (*Keuper, marnes irisées*) with gypsum, and the usual characters of the strata.

4. The muschelkalk, much as it occurs about the Vosges. It admits of subdivision into two, or, perhaps, three parts, which, according to Hoffman, may be distinguished by their respective types of organic remains.

3. Variegated sandstone. (*Bunter sandstein, grès bigarré.*)

2. Zechstein, or magnesian limestone formation, consisting of the following members:—

a. Rauchwacke, asche, stinkstein, &c. with gypsum.
Coloured marls.
b. Kupferschiefer and zechstein.

1. Lower red sandstone, (*Rothetodteliegende, grès rouge,*) which is often associated with porphyritic masses like the red sandstone of Exeter.

The following Table will show the relations of the three tracts.

England.	France.	Germany.
4. Variegated marls.	5. Marnes irisées.	5 Keuper.
	4. Muschelkalk.	4. Muschelkalk.
3. Variegated sandstone.	3. Grès bigarré.	3. Bunter sandstein.
2. Magnesian limestone.	....	2. Zechstein.
1. Lower red sandstone.	2. Grès des Vosges. 1. Grès rouge.	1. Rothetodteliegende.

A more minute analysis of the zechstein and magnesian limestone series furnishes the following comparison.

England.	Germany.
Upper laminated limestone.	Stinkstein, Rauchwacke, &c.
Gypseous coloured marls.	Coloured marls and gypsum.
Yellow magnesian limestone.	Zechstein.
Marl, slate, and fishes, or limestone with shells.	Kupferschiefer, and fishes of Mansfeld.
Lower red sandstone.	Rothetodteliegende. (Upper part.)

Coal formation.

And we might by a diagram express the gradual change from one of these types to another, putting the Vosges section between those of England and Germany.

With respect to organic remains it may be sufficient to remark generally that they are found locally in

abundance in all the members of the saliferous series in Germany and France, while hitherto they have appeared in England confined to the two lowermost groups.

Salt.

It appears that the greater part of the salt beds of Germany occur in the muschelkalk, between Magdeburg and Osnabruck, and in the Valley of the Neckar in Würtemberg. At Vic, Baden, and Lons le Saulnier, salt lies in red marl, along the North side of the Tyrolean alps in red sandstone, (Altenau, Berchtolgaden,) and it is possible that the abundant salt-works on both sides of the Carpathians in Transylvania and Moldavia may be established on this series. The salt of European Russia (Strangways, in *Geol. Trans.*) is also connected with the new red sandstone; but the geological age of the salt amongst the sands (said to be red) of Persia, in India between the Indus and Chellum, in Africa, New Holland, and North America, is at present a matter of conjecture, though in the Valley of the Mississippi we recognise the characters of a red sandstone deposit. The salt of Cordova, in Spain, and various points along the line of the Pyrenees, appears to lie in green sand; that of the Salzburg alps belongs to alpine limestone of the oolitic area, while in Sicily salt is found in sulphureous tertiary marl, and at Wielitzka it lies in tertiary strata containing a few shells.

Circumstances attending the Origin of the Saliferous System.

Its marine origin.

From the preceding statement we may confidently decide that the whole of the strata belonging to the saliferous system were deposited in the sea around the previously elevated lines of older rocks. The mechanical aggregates of sandstone, and clays, and marls, do not in general show us those exceedingly fine laminations and indefinitely numerous alternations of different materials which mark the coal deposits, they do not abound in such a multitude of spoils of the land, nor contain extended layers of the reliquiæ of fresh water. Had he never known of the local accumulations of fossil plants in the Keuper and variegated sandstones of the Continent of Europe, the English Geologist might have consistently doubted whether inundations from the land had ever disturbed the regular operations of the sea during this period. To explain this irregularity of distribution of terrestrial plants, it may be supposed that inundations from the land happened only in particular places along the margin of that ancient sea, or it may be said that the inundations being general, the growth of plants was limited. With respect to the accumulation of the rocks themselves, equal difference of opinion may be indulged; for if the remarkable absence, from the greater part of the area of the saliferous sytem, of any marine exuviæ in the mechanical aggregates might favour the notion of the materials being wholly derived from the land, yet the mere fact of the extraordinary and connected extent, the remarkable *uniformity of character of these extensive deposits*, even where the more anciently elevated strata round which they were evidently formed are of entirely different nature, and their apparent *independence* of these boundaries of their surface, seem to prove either 1. that the materials were collected by the action of the sea itself; or 2. that when brought into it by other agents, they were for very long times exposed to its equalizing action.

This long action of the waves upon the particles of the silicious and aluminous rocks and minerals which compose the mechanical aggregates and sedimentary deposits of the saliferous system, is also suggested by the amazing prevalence of the colour of peroxide of iron, which covers as a varnish so many of the particles; and it is confirmed by the discoveries of the organic remains, since these are of such a nature as to prove that during the saliferous period the whole living creation of the carboniferous period came to an end, and was replaced by several peculiar tribes which likewise finished their career and yielded to the more numerous races which fill the oolitic rocks.

Prevalence of magnesia.

The calcareous portion of this system presents us with even more decisive evidence, from its organic remains, of its marine origin, but the circumstances which permitted the accumulation of the magnesian carbonates of lime are in great measure unknown to us. That they were originally deposited in the same chemical condition as we now see them, without the subsequent aid of any igneous operations, is perfectly evident; and the occasional occurrence of *pebbles and shells* of the carboniferous system in the magnesian limestone, coupled with the known fact that certain beds of the carboniferous limestone contain a large proportion of magnesia, might lead us to conjecture that the one is derived from the ruins of the other. But, as Professor Sedgwick observes in discussing this subject, (*Geological Transactions*,) all the magnesian beds in the carboniferous limestone would be quite insufficient for the purpose, and the *crystalline character* of the Mansfield and other varieties of magnesian limestone clearly negatives this mechanical solution. Beds rich in magnesia alternate with others devoid of that substance, the same beds are in one tract magnesian, in another yield pure lime, and in general we must be content to shelter our ignorance under the statement that from some unknown cause the waters of the sea were then decomposed in such a way as to permit very generally the precipitation of united magnesian and calcareous carbonates—the possible circumstances of which must be intrusted to the examination of the Chemist.

Salt and gypsum.

The salt and gypsum usually associated in this remarkable system present also their difficulties. Not that it is hard to suppose the waters of the ancient sea to have been so evaporated as to permit first the crystallization of sulphate of lime, and finally of muriate of soda. But in this case we should expect to find almost uniformly over the whole area regular strata of gypsum below, and regular layers of salt above, while, in fact, we more commonly find salt in great broad masses rather than beds below, and gypsum in scattered masses above. A general drying of the waters in which the saliferous system was deposited is plainly inconsistent with probability; and we must have recourse to local causes, something analogous perhaps to those which influenced the deposit of primary limestone. It may be conceivable that the solubility of muriate of soda in water is capable of diminution through the admixture of other substances in the liquid, or through the effects of great pressure, or of pressure and heat combined; it may be maintained that the limited deposits of salt happened in separated lagunes of the sea, exposed to local desiccation, as perhaps in Cheshire. Mr. Lyell has still a different and less probable view of the subject. All these explanations assume that the salt was produced directly by *mere* crystallization, from waters almost perfectly analogous to those of the actual seas; an assumption strongly confirmed

by the recent discoveries connected with bromine and iodine.

Further researches, both Chemical and Geological, must determine between these and other theories, and in particular, we must be more exactly informed of the ancient hydrography of the salt districts, which, in almost every instance, must have been very different from their present topographical features.

Table of the Organic Remains of the Saliferous System.

The asterisk distinguishes such as are known to occur in other systems of strata.

PLANTS.

Family.	Name.	Locality in Keuper.	Locality in Muschelkalk.	Locality in Pœcilitic Sandstone.	Locality in Magnesian Limestone.
Algæ	Fucoides Brardii				Frankenberg copp. slate.
	selaginoides				Mansfeld, ditto.
	frumentarius				Ditto.
	pectinatus				Ditto
	digitatus				Ditto.
	lycopodioides				Ditto.
Cryptogamia	Equisetum Meriani	Neue Welt near Basle.			
	*columnare	Würtemberg		Sulzbad, or Soultz.	
	platyodon	Franken in Würtem.			
	Calamites arenaceus	Ditto		Wasselone, Marmoutier.	
	Mougeottii			Marmoutier.	
	remotus			Wasselone.	
	Pecopteris Meriani	Neue Welt.			
	*arborescens				Near Autun.
	*abbreviata				Ditto.
	Tæniopteris *vittata	Neue Welt, Stuttgart.			
	Anomopteris Mougeottii			Soultz, Wasselone.	
	Neuropteris Voltzii			Soultz.	
	elegans			Ditto.	
	Gaillardoti		Luneville.		
	Sphænopteris myriophyllum			Ditto.	
	palmetta			Ditto.	
	Filicites Stuttgartensis	Stuttgart.			
	lanceolata	Ditto.			
	scolopendrioides			Ditto.	
	Lycopodites Hœninghausii				Eisleben near Mansfeld.
Cycadeæ	Pterophyllum longifolium	Neue Welt.			
	Meriani	Ditto.			
	Jægeri	Franken, Stuttgart.			
	enerve	Neue Welt.			
	Mantellia cylindrica		Ditto.		
Various families.	Convallarites erecta			Ditto.	
	nutans			Ditto.	
	Palæoxyris regularis			Ditto.	
	Echinostachys oblongus			Ditto.	
	Æthophyllum stipulare			Ditto.	
	Marantoidea arenacea, Jæger.	Stuttgart.			
	Voltzia brevifolia			Ditto.	
	elegans			Ditto.	
	rigida			Ditto.	
	acutifolia			Ditto.	
	pterophylla			Ditto.	
	Asterophyllites ? bullosa				Thuringerwald.

The following plants, which are well known in the coal strata, occur in the lowest red sandstone. (Rothetodteliegende.)

*Lepidodendron Sternbergii	Hinkelheim in the Spessart.
*imbricatum	Werderbruck near Rothenburg.
*Stigmaria Veltheimiana	Magdeburg ?

Other vegetable relics at Amrode, Seibigkerode, between Friedeburg and Rothenburg, Kyffhaeuser, Meisdorf, Endorf.

The names in this list are taken from M. Brongniart, who supposes the flora of the variegated sandstone system to be of a peculiar type. It is certainly very analogous to that of the succeeding or oolitic epoch, by its pterophylla and equiseta, but the genus Voltzia is perhaps peculiar to it.

POLYPARIA.

Name.	Locality in Magnesian Limestone.
Gorgonia anceps, Goldfuss.	Glücksbrunn in Thuringerwald.
antiqua, G.	Glücksbrunn.
infundibuliformis, G.	Ditto.
*Calamopora spongites, G.	Ditto, (and Ural.)
Retepora flustracea, Phil.	Durham.
virgulacea, Phil.	Ditto.
Astræa pediculata, D.	

The absence of polyparia from the muschelkalk is one of the characters by which it approximates to the lias.

Radiaria.

Name.	Locality in Keuper.	Locality in Muschelkalk.	Locality in Magnesian Limestone.
Ophiura prisca, Mün.	Vosges Mountains	Baireuth.	
loricata, G.	Schwenningen.		
Asterias obtusa, G.		Marbach.	
Encrinus moniliformis, Mil.		General in this rock.	
ramosus, Schl.			Glücksbrunn.
Pentacrinus dubius, Gold.		? Rudersdorf.	
*Cyathocrinus planus, Mil.			Durham.

Annulosa.

Name.	Locality in Muschelkalk.
Serpula valvata, G.	Baireuth.
colubrina	?

By its radiaria, amongst which no echinus is mentioned, the muschelkalk resembles the lias; those radiaria which lie in the magnesian limestone present greater analogies to the older rocks.

Conchifera.

Family.	Name.	Locality in Keuper.	Locality in Muschelkalk.	Locality in Pœcilitic Sandstone.	Locality in Magnesian Limestone.
Plagymyona.	Cardium pectinatum, v. Alberti	Wurtemberg	Würtemberg.		
	striatum, Schl.		Ditto, Göttingen.		
	Trigonia vulgaris, Schl.	Ludwigsburg	Weimar, Göttingen, Würtemberg, Baireuth	Domptail, Soultz.	
	curvirostris, Schl.	Ditto, Schwenningen.	Würtemberg.		
	sulcata, G.	Villingen.			
	pes anseris, Schl.		Göttingen, Morsbach, Luneville.

GENERAL SUMMARY.

Plants......	Marine....................	6;	wholly confined to the zechstein.
	Cryptogamia	23;	of which six are stated to occur in other systems of strata.
	Gymnosperma, &c.........	17.	
Zoophyta ...	Polyparia	7;	all confined to the zechstein group; one found in another system of strata.
	Radiaria	7;	confined to the muschelkalk and zechstein; one repeated in carboniferous limestone.
Articulosa...	Annulosa	2	in muschelkalk.
	Crustacea	1	
Mollusca....	Conchifera plagymyona	32;	eight of these occur in England in magnesian limestone.
	mesomyona	32;	three of these occur in England in magnesian limestone.
	brachiopoda	28;	eight of these occur in England in magnesian limestone.
	Gasteropoda holostomata ...	17;	four of these occur in England in magnesian limestone.
	solenostomata	3.	
	Cephalopoda..............	6.	
Fishes	....	15;	four occur in England in magnesian limestone.
Reptiles	....	9.	
		205;	of which about thirty occur in England in magnesian limestone.

Disturbances of the Saliferous System.

In England dislocations of a very extensive nature are but rarely exemplified in strata more recent than the coal measures. It appears that this part of the surface of the Globe enjoyed a long and rarely interrupted immunity from those violent agencies which had previously shaken its strata into such disturbed positions. A few faults in the magnesian limestone range of Durham and Yorkshire, as along the line of the great whindyke through those Counties, in the country between Doncaster and Ferrybridge, and South of Doncaster, may be mentioned rather as exceptions to the general rule, effected in some indefinite portion of the long period succeeding the deposit of coal; and the curious parallel faults of Aust cliff on the Severn, which affect both the lias and red marl, deserve attention, in connection with the law formerly laid down of faults underlying depressed portions of strata. (p. 511.)

Neither on the Continent of Europe are the dislocations of the saliferous system so remarkable as those of the older strata. In the Vosges mountains we have, however, a splendid example of a dislocation on a great scale, by which, in a direction North-East and South-West, the lower strata of this system (*grès des* Vosges) are thrown up into bold mountains, while the upper beds of the same system (muschelkalk and keuper) are left several hundred feet below the magnificent escarpment. In fact, it appears that this eruption happened during the saliferous epoch, after the date of the grès des Vosges, and before the muschelkalk and keuper were deposited.

In the South-West of Brittany, in La Vendée, in Morvan, De Beaumont describes dislocations which appear to have preceded the lias; and from observations on the Böhmerwald and Thuringerwald it appears that the elevation of these ranges of mountains followed the saliferous epoch, and preceded the lias and oolites. Of the same era are some dislocations defining the primary ranges near Avallon and Autun.

Several cases, then, appear to show unconformity and interruption of continuity between the variegated marls and the oolitic formation above. But these are but local effects; parallelism of strata generally prevails between these contiguous systems, indicating freedom from general disturbance, and in some instances, especially in Somersetshire, the frequent changes of colour in the upper red marls, and finally the interposition of a purple or black marl, which is not more related to the lias than to the saliferous system, appear to show that even in the nature of the deposits there is no more decided difference between them than between any other successions of strata.

Oolitic System.

The oolitic system of strata has for the most part its ranges parallel, and its declinations accordant to the saliferous rocks, and was deposited in the same marine basins. The general character of the rocks, and the nature of the organic remains is however extremely different, but the change from the one system to the other, though seldom to be called gradual, is accomplished by remarkable repetitions. In particular, the muschelkalk of Germany and France represents, even in mineralogical characters, but most decidedly in its suite of organic exuviæ, the lias, which is at the base of the oolitic system. Through all the mass of the oolitic system, consisting of various limestones, clays, and sands, the most remarkable repetitions occur. The mass of lias contains beds very nearly approaching to the ferruginous inferior oolite; three or four separate beds of very similar oolite, several beds of sand and sandstone also remarkably analogous, and many thick strata of clay hardly distinguishable except by their organic reliquiæ, make up this vast argillo-arenaceo-calcareous mass, of which the top changes, by repeated introductions of green sand layers, to the real cretaceous system, as the bottom has been before shown to be connected with the saliferous group.

The composition of this system varies much in different Countries of Europe, according, probably, to the differences of depth of the original waters, proximity to land, to mouths of ancient rivers, &c. In consequence, while on the border of Swisserland it is almost wholly calcareous, in Westphalia and in England its limestones are much intercalated with clay, and occasionally with carboniferous sandstones and shales, hardly to be distinguished from those of the older coal strata. A remarkable absence of metallic substances is a character of the calcareous portions of this system (excepting the lias) in all its extent.

The most distinct classification of the oolitic system will be obtained from the combined section of the English series; for though the total thickness of the deposit is perhaps greater in the South East of France and in Swisserland, the number of divisions is there less, the mass more uniformly calcareous, and the parts less characteristic.

The oolitic system of England everywhere admits of

the following mode of subdivision, though in some tracts particular groups are concealed by unconformity or entirely wanting. The groups are placed as they occur in nature, or the series is descending.

5. Wealden formation.	A series of clays, sandstones, and limestones, mostly of fluviatile origin, and containing remains of land and fresh-water animals and plants, deposited in estuaries or other local hollows of the really marine portion of the oolitic system.
4. Upper or Portland oolite formation.	Calcareous, sometimes oolitic rocks, associated with green and irony sands, resting on blue clay, altogether marine deposits. When the Wealden formation is absent (as happens in the greater number of instances) this terminates the whole system, and graduates into the cretaceous rocks above.
3. Middle oolite or coralline formation.	Consisting of oolite and other limestone strata, included in calcareous gritstones, and resting on blue clay and calcareous gritstone: altogether marine deposits.
2. Lower or Bath oolite formation.	Consisting of two or more strata of oolite, with other calcareous beds, and alternations of sands and clays, which in particular districts enlarge themselves into real coal tracts. Altogether marine and littoral deposits.
1. Lias formation.	Consisting principally of argillaceous clays, more or less laminated, and including, especially in the lower part, layers and nodules of generally argillaceous limestone, and in the upper part bands and strata ferruginous, calcareous, and arenaceous, which strongly resemble the bottom of the lower oolite formation.

Oolitic System.

A further analysis of these formations presents us with the following details.

5. Wealden formation of Kent, Sussex, and Hampshire.		*Weald clay.* Thick blue clays, generally destitute of organic remains, except in certain calcareous beds, which contain fresh-water shells.
		Hastings' sands. Thick series of sandstones, with partings of clay, and subordinate beds of limestone, with bones of saurians, fluviatile shells, and land plants.
		Purbeck beds. Blue clays and laminated limestones with fluviatile shells.
4. Upper oolite formation of Portland, Wilts, Bucks, Berks, &c.		*Portland oolite.* Oolite and earthy and compact limestones with marine shells, and layers of nodular chert.
		Shotover sand. Calcareous sand and concretions.
		Kimmeridge clay. Thick blue clay, bituminous, with septaria and marine remains, and especially in the lower part, bands of sandy concretions, thus establishing a gradation to the next system.
3. Middle oolite formation of Oxford, Berkshire, Yorkshire, &c.	Coralline oolite group.	Upper calcareous grit, with marine fossils.
		Coralline oolite, so named from two or three separate beds of irregular occurrence, rich in zoophytic exuviæ. In the lower part the beds alternate with those of the next rock; all of them contain marine exuviæ.
		Clay 10 feet. Lower calcareous grit, with marine shells, graduating below into the Oxford clay.
	Oxford clay group.	Oxford clay, with septaria, fossils, &c.; the lower part a subordinate bed, called
		Kelloway rock, which is a calcareous grit, (rarely oolitic,) very rich in fossils.
		Blue clay dividing Kelloway rock from the cornbrash.
2. Lower oolite formation in Gloucestershire, Oxfordshire, and Northamptonshire		Cornbrash limestone, a coarse, shelly rock of variable and small thickness, but remarkable continuity.
	Forest marble group.	Sand with concretions of sandstone and nodules of fissile arenaceous limestone.
		Coarse shelly oolite, in some places slaty.
		Sandy clay or grit.
		Blue clay.
	Great oolite.	A calcareous and mostly oolitic rock, of variable thickness and changeable nature, the upper beds shelly.
	Fuller's earth group.	A series of marls and clays with included beds of soft marly or sandy limestones and shells.
	Inferior oolite.	A coarse, often very shelly rock of limestone, irregularly oolitic, occasionally interlaminated with sand, especially in the lower part.
		Ferruginous sand with concretionary masses of sandy limestone and shells.
1. Lias formation in Yorkshire, Northamptonshire, and Somersetshire.		Upper lias clay or shale, full of belemnites and other fossils, intercalated with or graduating to the sand above, and in some cases containing nodules and bands of limestone.
		Marlstone. A suite of calcareous, sandy, and irony beds, very rich in fossils, and much analogous to the lowest bed of the lower oolite formation.
		Lower lias clay or shale, full of fossil remains, interlaminated with bands and nodules of limestone, especially in the lower part, where a collection of these layers constitutes the lias rock.
		Lias rock. A suite of laminated limestones, with partings of clay, blue, grey, and white, the former in particular containing gryphites and other shells; the latter usually devoid of organic remains. This rock is sometimes consolidated into a united mass, and sometimes divided into separate portions. It rests on the red marl in the North of England, and on blue, black, or purple marls, which cover that formation in the South of England.

N. B. All this part of the series is differently composed in Yorkshire and the North of Scotland.

The lias formation is observed on the Southern coast of England, at Lyme Regis, from whence passing under the unconformable green sand of Blackdown, and surrounding the irregular elevations of carboniferous limestone in Somersetshire, it ranges uninterruptedly by Bath, Gloucester, Leicester, Newark, and Gainsborough, to the Humber. At this point the course of the oolitic system is very much narrowed by the overextension of the chalk; and at Bishop Wilton the chalk rests on the lowest part of the lias formation, which has a superficial breadth of only a few yards. It, however, expands again towards the North, and shows itself very completely developed on the coast of Yorkshire. Detached portions of this formation accompany the saliferous system in Glamorganshire, and lie unconformably in the hollows amongst elevated ridges of carboniferous limestone.

Through the whole of this range some general physical features, almost constant mineralogical qualities, and prevalent species of organic reliquiæ, fix such a decided character upon the lias formation as to establish a good geological horizon for the guidance of the English observer.

The country which it occupies is in general a broad vale at the foot of the escarpments of oolite, and terminating towards the red marl by a very connected range of uniform low hills. A considerable portion of the steep slope of the oolite escarpments is occupied by the lias; and in the Midland Counties, particularly, owing to the action of currents of water, detached portions of

oolite crown the summits of many insulated masses of the upper lias shales.

From the coldness and stiffness of the soil, much of the surface of the lias clays remains in pasture, for which it is particularly well adapted; and where the plough has in former times been employed, the land is thrown up into very high ridges for the sake of surface drainage. Water is scarce in this tract, and, because of the abundance of pyrites, often sulphureous or ferruginous, or impregnated with purgative salts, as sulphate of soda.

A general tendency to an argillaceous type belongs even to the limestones of the lias formation, and its clays more frequently exhibit a schistose structure than the other clays of the oolitic system. Layers and masses of jet are frequent in it, especially in the Northern part of its course; pyrites is one of its most abundant productions, especially in connection with ammonites and other shells, and sulphur in some parts is so prevalent as to furnish a valuable manufacture of alum. Many fruitless trials for coal along the line of the lias clays are upon record, to serve as a warning to those unacquainted with Geology.

Very remarkable organic exuviæ belong almost equally to every part of the English lias. Skeletons of saurian and chelonian reptiles, several species of scaly fishes, abundance of ammonites and belemnites, plagiostomata, gryphææ, &c. and considerable quantities of the wood of coniferous trees, enable the Naturalist to form very reasonable views of the state of the ancient land and sea when this formation was in progress, and serve not only to identify it in all parts of England, but even over a large part of its extent in France and Germany.

Nevertheless, there are important geographical peculiarities connected with the lias of England, which deserve a short analysis, the better to enable us to perceive the circumstances under which the ancient sedimentary deposits of the sea took place.

Lias in Yorkshire.

The section of the lias, as it exists in Yorkshire and Lincolnshire, is peculiarly instructive and complete, and forms an excellent type with which to compare the detached portions of the formation in North Britain and the South of England. We shall take the groups in the ascending order of their antiquity.

Lias limestone. The calcareous beds included in this division are in the North of England very distinctly divided into two or more portions separated by considerable thickness of clay.

1. The lower limestone, 10 to 20 feet thick, is not traced further North than the Humber. It consists of compact blue or grey limestone, generally laminated and shelly, with partings of whitish clay or marl. It rests immediately upon the red marl and gypsum.

2. Clay, 50 to 100 feet, with layers of nodules, often septariate, full of pentacrinites, ammonites, plagiostomata, &c.

3. Upper lias limestone, 12 to 20 feet, in rough, shelly, coarsely laminated beds, separated by partings of clay. The colour usually brown, but in wet pits and before exposure to the air internally blue. But the most remarkable character of these beds is the astonishing abundance of gryphæa incurva which they contain, or rather of which they almost wholly consist. In several parts of Lincolnshire the roads are mended with the most beautiful specimens of this fossil, and for miles together hardly any other shells can be collected from this part of the lias.

Lower lias clay or shale, 300 to 500 feet thick, a dark homogeneous clay or shale, with many layers of argillo-calcareous nodules, seldom containing shells, and in the lower part rough sandy beds. Coniferous wood, pentacrinites, plicatulæ, gryphæa Maccullochii, pinna folium, and several ammonites, &c. occur in this stratum, but in it organic remains are not particularly abundant, and neither belemnites, terebratulæ, nor saurians are so plentiful as in the beds above. No alum is made from this part of the lias shale.

Marlstone series, 100 to 150 feet, consisting of highly arenaceous shales, and laminated sandy limestones of brown, greenish, or grey colour, succeeded above by several bands of nodular ironstone, the whole series particularly abundant in shells, besides producing beautiful stellerida, annulosa, and fishes. Several species of terebratulæ, cardium truncatum, dentalium giganteum, &c. appear almost confined to these strata, which likewise contain gryphææ, pectines, plagiostomata, terebratulæ, and modiolæ, not distinguishable from the ordinary fossils of the oolite. The marlstone beds are in fact the first term of the oolitic deposits, interpolated among the last terms of the lias, and, according as the clay above them is attenuated or developed, they may be ranked with the oolitic, or the lias formation. In the North of England, the former mode of arrangement *must* be adopted, but in the South, the latter has been often followed.

The upper lias clay or shale, 50 to 200 feet in thickness, is the aluminous rock of Yorkshire, and passes by intermixture into the marlstone series below, and by a gradual change into the analogous sandy beds of the oolites above.

It contains a multitude of layers of argillo-calcareous nodules mostly aggregated round ammonites and other organic bodies, and these are particularly remarkable and of larger size in the lower part of the shale, which also is much harder than the rest. A profusion of ammonites, belemnites, and nautili, accompanied by aviculæ, inocerami, amphidesmata, &c., besides abundance of ichthyosauri, and plesiosauri, jet, and remains of coniferous wood, enrich this interesting rock. Its thickness is variable, amounting to 200 feet on the coast, but diminished to 50 feet, or even less, in some of the Cleveland hills, where also the usual smooth homogeneous texture of aluminous shale is changed to a decidedly sandy composition.

Lias in Midland Counties.

Proceeding to the South, we find the characters of the lias formation of Yorkshire maintained with considerable exactness through the Counties of Nottingham, Lincoln, Leicester, and Rutland, into Oxfordshire. The section from Lincoln to Gainsborough shows clearly the upper lias clay, marlstone group, lower lias clay, gryphite limestone, and laminated limestone, all superimposed on gypseous red marl. In the vale of Belvoir, likewise, through Rutland, and as far as the centre of Oxfordshire, we have the lower laminated limestone (1.) surmounted by a thick clay, (2.) in which lie gryphitic beds peculiarly shelly, which Mr. Conybeare calls *upper lias* beds, and which correspond to the gryphitic beds of Lincolnshire. Still higher, are beds of green or brown marly sandstone, with terebratulæ, pectines, belemnites, and other shells, which are always ferruginous, and, in Rutland particularly, laminated and entirely similar to some of the marlstone beds of Yorkshire. Above these, in the same tracts, lie 100 or even more feet of clay, often forming insular

Geology. Ch. II.

hills between valleys of marlstone, and upon the whole the ferruginous sand of the inferior oolite.

If any doubt has at any time been raised as to the real distinction in this country of upper lias clay, marlstone, lower lias clay, and double course of lias limestone, it has probably arisen from the extreme resemblance of the ferruginous marlstone of the Vale of Belvoir which divides the upper from the lower lias clay to the ferruginous sandstone which is the general floor of the oolitic rocks. In Rutland, however, the distinction is perfectly evident.

Lias of the Cottswold.

Through Oxfordshire and Gloucestershire the upper lias clay continually becomes thinner, and the marlstone beds in consequence approach nearer to the sand of the inferior oolite. It is no wonder, therefore, that they should be in these Countries sometimes confounded. But the section of Painswick Hill, near Stroud, adduced by Mr. Conybeare, (*Geology of England*, p. 252.) sufficiently proves that the same principle of classification applies to the lias below the Cottswolds, as well as to the North-East moorlands of Yorkshire. In fact, by merely taking the argillaceous beds which in this section separate the sands of the oolite from those of the marlstone, and calling them upper lias clay, the accordance with the Yorkshire section is perfectly evident. This question has been effectually settled by Mr. Lonsdale's recent and most valuable investigation of the Cottswolds. That excellent observer has clearly established the identity of the lias system of Gloucestershire with that of Yorkshire, in general terms; at the same time defining the amount of topographical difference which principally affects the upper lias shale.

In the Southern parts of Gloucestershire, and in the vicinity of Bath, the upper lias clay becomes still more attenuated, and the marlstone beds more divided and mixed with the clay. Mr. Smith gave the name of marlstone to the laminated stony beds full of pectines and other shells which are found in the Somerset canal and other places, twenty feet or less below the sand of the inferior oolite, as may be noticed in his sections. In several places, these beds, from the deficiency of the clay above, are brought nearly into close contact with the sand of the inferior oolite.

Whether this distinction of marlstone beds can be carried further South into Dorsetshire does not yet appear.

From Mr. Lonsdale's Essay in the *Geological Transactions*, we find the lias limestones to be thus arranged in the descending order.

	Feet.
Blue lias. Consisting of beds of greyish argillaceous limestone, varying in thickness from 2 to 18 inches, and separated by others of blue marl which are generally less than 6 inches thick, but sometimes more than 2 feet	50 to 60
White lias. Thin strata of yellowish white argillaceous limestone, with partings of pale brownish clay	10
Lias lower marl. Dark grey marl with calcareous concretions	20

Organic remains of ammonites, belemnites, pectens, oysters, &c. though most abundant in the blue lias, are more or less diffused through all the beds.

Combining the section of the North of England with Mr. Lonsdale's and Mr. de la Beche's sections of the lias in the vicinity of Bath and Lyme, we shall have the following general table of the complete type of the English lias.

1. Upper lias clay, marl, or shale..	Upper lias shale (Phillips.)
2. Marlstone beds.	
3. Middle lias clay	Upper lias marl. (Lonsdale.) Lower lias shale. (Phillips.)
4. Lias limestones and marls ...	Gryphitic and laminated lias of North of England. Blue and white lias of Bath.
5. Lower lias marls	Of Lyme Regis and Bath.

These lower marls are thus described by De la Beche, at Culverhole, near Lyme, (section descending.)

	Ft.	In.

Lias in North Britain.

Mr. Murchison's *Memoirs on the Oolitic Deposits of North Britain*, most clearly prove the existence of well-characterised lias shales, much like those of the Yorkshire coast, in Pabba, Skye, and other of the Western Isles, and the organic remains which he collected there are of the usual English types. Lias occurs also on the North-East coast of Ireland, as at the Giant's Causeway, with ammonites and belemnites.

The lias in South Wales is a singular extension of the formation among the dislocations of the older carboniferous system, nearly analogous to its appearance among the sandstones and slates of Scotland. The Valley of the Ely, in South Glamorganshire, exhibits several upfillings of lias, commencing about five miles West of Landaff, whence, with some interruptions, they accompany the Ely to its junction with the Channel near Penarth Point. It again appears in Barry Island, and continues to skirt the coast in a Westerly direction nearly to the mouth of the Ogmore river, forming a range of bold cliffs, among which is the little harbour of Aberthaw, celebrated for the lime which it exports. (Conybeare, *Geology of England*.)

Lias in France and Germany.

We may now turn our attention to the general types of lias presented in the North and South-East of France, and in various parts of Germany.

As in England, so generally in these Countries, the lias is deposited conformably to the saliferous system, but in Brittany and around the plateau of primary rocks in central France, especially about Autun, the oolitic system often touches the granitic series without any interposition of red sandstones. In the district which borders that plateau on the East, between Chalons and Autun, the oolitic rocks are considerably developed with lias at the bottom, and all based upon gypseous red marl; but the lias clays are here almost wholly deficient, and the formation consists only of the gryphitic limestone, with its partings of clay. The abundance of gryphæa incurva, and other characters of the stone, strongly remind the traveller of the analogous beds in Lincolnshire. The lias and oolites are so closely allied that Desnoyers, in his description of this tract, hesitates even to distinguish the former as a fourth stage of the calcareous or oolitic system.

South of the Ardennes mountains by Luxemburg, Metz, and Nancy, the lias exhibits more developed characters. Immediately upon the Keuper marls rests a considerable bed of sandstone, white, yellow, or rarely brown, sometimes solid, and sometimes friable; gradually passing into the lias beds above. From its

abundance under and around the fortress of Luxemburg, it receives in that Country the name of *grès de Luxemburg*.

The proper gryphitic lias limestones succeed and cap most of the plateaux of grit. The beds are bluish and compact, and alternate with grey friable marls.

Above are grey marls and marly grits, which correspond to the lias clays and marlstone of England; and these are followed by the ferruginous sandstones which form the general floor of the oolitic system.

In Würtemberg, and, perhaps, generally on the German side of the Rhine, the lias has more of the character of the English series both as to mineralogical composition and organic remains. In particular, the saurian reliquiæ, so abundant in the lias clays of England, are all found in those of Boll and other parts of Würtemberg, and with some additional species have been described by M. Jäger, of Stuttgart. Fine specimens of saurian animals occur in many of the museums along the Rhine. But, perhaps, the most remarkable accordance between the series of Germany and that of England, is observed at Banz near Coburg, where the Maine crosses the Northern extremity of the Franconian range of oolites. Here Mr. Murchison has observed the following section.

Sandstone cap of the lias	300 feet thick.
Upper lias shale of Yorkshire	40
Marls and marlstones	150
Lower lias shale, with compact lias and ammonites Hawkerensis, near the top	300
Gryphite limestone	
Gritstone	
Keuper formation	

At this place the most astonishing profusion of saurians, fishes, crustacea, ammonites, nautili, and belemnites, as well as pentacrini, gryphites, and other fossils, occur, and many of them remarkably agree as to their place in the strata with the arrangement of the same species in the beds of the coast of Yorkshire.

Lias shales occur below the Alpine or Jura limestone of Swisserland and Savoy, and occasionally, as at Meyringen, Bex, the Mont Joux, produce some of the characteristic ammonites and belemnites of the English lias. In the Valley of the Arve, in particular, the argillaceous beds of lias are immensely thick, and owing to the igneous agency, once so powerfully excited beneath the Alps, have a schistose character strongly assimilating them to the primary slates. Whether the slates of the Valorsine belong to the same era is, perhaps, not yet ascertained; but if this should be proved, the vegetable remains which they contain, being identical with those of the carboniferous epoch, would indicate that these regions enjoyed a particular immunity from the causes which, in all other instances yet examined, had wholly destroyed the plants which grew in the carboniferous epoch, and covered the earth with cycadeæ and other entirely new types of vegetable life.

Lower Oolite Formation.

The uninterrupted range of this formation through Dorset, Somerset, Gloucestershire, Oxon, Northamptonshire, Rutland, and Lincoln, to the banks of the Humber, may be seen on the Maps of Mr. Smith or Mr. Greenough. Beyond the Humber it is concealed for a short distance beneath the overlying chalk, but emerges again, and occupies a vast breadth in the Eastern part of Yorkshire. In Sutherland, and in some of the Hebrides, and particularly in Skye, it has been traced by Mr. Murchison.

It occupies, through all its course in England, an elevated range of hills with bold escarpments to the West or North-West, a gentle slope to the East or South-East, and deep valleys of denudation which often, by descending to the lias clays, furnish most complete information as to the relations of the two formations. The surface of the calcareous portions is dry and bare of trees, and wells sunk therein often reach a very considerable depth, while upon the alternating clays the soil is cold or wet, and, in general, much covered by woods. The fertility of the district is below the average of the secondary strata. The highest point of the range in the South of England is Cleeve Pipard Hill, near Cheltenham, 1134 feet above the sea, and in the North of England, Botton Head, near Ingleby in Yorkshire, 1485 feet; but in these cases about two-thirds of the height consists of the lias clays.

The more ordinary altitudes of the oolitic range in England are 700, 800, and 900 feet, varying according to the Westward extension of the hill, the thickness of the base of lias, and the pile of incumbent strata.

Escarpments of oolite.

Certainly, this regular and continuous range of oolites, with so nearly uniform an elevation of escarpment, is one of the most characteristic features of English Geology, and furnishes matter for profound reflection. For like the parallel, equally continuous and regular, and but slightly lower range of chalk, its elevation seems not at all due to local disturbances, but rather appears to indicate a general intumescence of the land in the direction of these ranges. The low vales of lias, Oxford clay, and Kimmeridge clay, which intervene between the lower, middle, and superior oolite ranges, have undoubtedly been caused, at least in part, by the erosive action of water; but to whatever extent we apply this principle in explaining the present inequality of the earth's surface, and whatever aid we receive for the established data of local elevation, these limited agencies always leave unexplained the general fact, *viz.*, the regular altitude of continuous ranges of hills with uniformly declining planes, and no particular marks of convulsion, which overlook extensive undisturbed plains of older strata.

The vicinity of Bath, where Mr. Smith began his important researches, furnishes the general type of the lower oolite formation; and, with some modifications, the series of strata here presented, as detailed by Mr. Smith and Mr. Lonsdale, is found to be almost universally reconcilable with the phenomena of the other oolitic districts. The variations observed are principally caused by the interpolations of a larger proportion of arenaceous, argillaceous, and carbonaceous beds, so as in extreme cases to change the calcareous section of Bath into a coal field, with subordinate beds of limestone. Such is especially the case in the Eastern moorlands of Yorkshire, at Brora in the Hebrides, and in the gorge of the Weser at Minden, as observed by Mr. Murchison.

The table of classification given above, will make known the order of succession of groups recognised in this formation, and we shall now proceed to point out their characters and notice their variations more exactly.

Inferior oolite group.

The Sand which is the base of the inferior oolite group in the vicinity of Bath, possesses, in general, only a slight degree of cohesiveness, but in places passes into a friable sandstone. It is micaceous, of a yellow colour, and contains irregular courses of calcareous concretions

Geology. Ch. II.

called sand burrs. These nodules are often aggregated round ammonites and other organic bodies. The thickness of this bed sometimes amounts to 70 feet.

The inferior oolite varies in thickness, in some places being 60 feet, in others considerably less. The rock, according to Lonsdale, admits of being characterised in three portions, the lower one 6 feet, hard, of a brown colour, abounds in casts of trigoniæ, limæ, trochi, &c., and is seen in many sections reposing immediately on the sand. The coated muscles, as they are termed, are found in this bed, and the bed which in the descending quarries yields so immense an abundance of species is apparently of the same date. The middle division, 10 feet, is a rubbly stone; principally consisting of crystallized carbonate of lime, through which the organization of astreæ may be clearly traced. It is, therefore, a coral bed, and as might be supposed is of irregular occurrence.

The upper portion of the rock, 40 to 50 feet at the utmost, contains the workable freestone or oolite of this rock, the upper part, in particular, cannot be distinguished in specimens from the great oolite above. The lower beds are more sandy, browner, and less oolitic.

The fuller's earth group.

The fuller's earth group, so named from the occurrence in it of limited beds of that substance, is a thick argillaceous deposit with a few layers of nodular limestone and indurated marl, occurring on the hill sides of Bath, and distinctly separating the inferior from the great oolite. The following is Mr. Lonsdale's summary of these beds.

	Feet.
4. Blue and yellow clay with nodules of indurated marl	30 to 40
3. Bad fuller's earth	3 to 5
2. Good fuller's earth, brown or blue	2½ to 3
1. Clay containing beds of bad fuller's earth and layers of nodular limestone (fuller's earth rock) and indurated marl	100

The great oolite rock.

The great oolite rock contains, besides the more perfectly oolitic parts, which hold few shells and furnish the best freestone, a great number of beds, in which the oolitic structure is less evident or even wanting, and which are more or less filled with remains of shells, corallines, &c. These coarser portions of the rock lie at the top and bottom, and enclose the purer oolite between them.

The lower rags consist of several beds of coarse shelly limestones 10 to 40 feet; the lowest bed of it which rests on the fuller's earth group is fine-grained and scarcely oolitic.

The oolitic beds in the middle are very variable in thickness and quality. On Combe Down the thickness sometimes amounts to 30 feet. The stone when taken from the quarry is quite soft, and holds so much water as to be beaten to a pulp by the hammer. After being thoroughly dried it will absorb more than one-seventh of its weight of water, but by long exposure it grows harder and less absorbent. It will not stand the sea air, though in the neighbourhood of the quarries it is very durable.

The upper rags, 20 to 55 feet, consist of alternating beds of coarse shelly limestones, tolerably fine oolite sand, tough, brown, argillaceous limestone. The shelly beds were used by the Romans in their buildings at Bath, and are thought to be very durable, but are difficult to work. Some of these beds are full of millepores and other polyparia and species of echini, and a profusion of minute univalve and bivalve shells. They often exhibit that peculiarity of internal lamination called false bedding, when the ingredients of the stone form layers inclined to the plane of stratification.

Geology. Ch. II.

The forest marble group.

The forest marble group admits of the following subdivision in a descending order:

	Feet.
